への取り込みは知られている。吸入経路からは中枢神経系への取り込みも明らかになっている。これらの取り込み過程は、粒子のサイズや表面の物理化学的性質に大きく依存しており、一概に述べることはできないが、条件がそろえば、生殖器官への再分布や血液-胎盤関門通過の可能性も否定できないと考えられる。まずは、これらの器官や胎児等へのナノマテリアル粒子の分布の可能性についての知見の集積が求められるであろう。

E. 結論

生殖発生毒性に関する知見はほとんど報告されていないが、肺、腸管および皮膚などの組織からのナノ粒子の体内への取り込み、その後の免疫システムや体循環、さらには中枢神経系への取り込みの知見からは、生殖器官や胎児への再分布も否定はできないと考えられた。

ナノマテリアルの安全性確認に必要な生体影響試験に関する緊急調査
分担研究報告書

本研究の生体反応分子の側からの蓋然的生体影響の検討

分担研究者　井上　達　国立医薬品食品衛生研究所
安全性生物試験研究センター長

研究要旨　生物を構成する細胞には、ミクロゾーム、ゴルジ装置、ミトコンドリアなどの様々の細胞内微細装置が 10nm フィラメントのネットワークに包まれて細胞質に存在し、まさにナノマシーンとして核からの情報物質との相互作用をもって様々なその機能の発現に役割を果たしている。他方、本研究で対象となるナノ物質は、それが特定構造をもった化学品であれ、非意図的な生成物であれ、ほぼ同次元の構成物として、先の生体材料と、生体との相互応答を構成することとなるので、ここに生物学的な応用の展望が様々に期待されると同時に、生体の利得の側から見たときに好ましくない影響の発現する可能性も想定されることになる。両者は表裏一体の関係にあり、従って、ナノマテリアル問題は、その表裏の関係に原点を置いて検討されることが必要である。

A．研究目的

意図的に 100nm 未満のいわゆるナノサイズ物質を製造する技術を得るに至って、新たに展開されつつあるナノ物質と生体の生体異物相互作用を生物学的蓋然性の面から検討する。

B．研究方法

以下の5項目について、生体機能修飾の蓋然性あるいは可能性について、必要な情報の収集とともに検討、考察した。

1．物質のカテゴリー分類
2．マクロ浸襲経路
3．生体内分布
4．細胞内機能移行
5．細胞表面分子との相互作用

（倫理面への配慮）

ここで用いられる実験動物の取扱いについては、世界保健機関で動物を用いる生物医学研究のための国際指針を設け、これらに配慮するに至った動物愛護の問題に真摯に受けとめ、動物の福祉の観点から、必要な動物の不安や苦痛の排除もしくは低減等に格段の配慮に努めることをもって動物実験に関する倫理面への配慮に努める方針である。但し、本研究においては

調査が主体となるので、さしあたりの研究の直接的な配慮は、必要ないものと考えられる。

C．D．研究結果と考察

以下の5項目について、生体機能修飾の蓋然性あるいは可能性について、必要な情報の収集とともに検討、考察した。

1．物質のカテゴリー分類

意図的ナノ物質、非意図的ナノ物質、化学品、化合物、混合物、などに分けて、実体的な暴露態様を文献的情報等を用いて整理することの重要性が明らかとなった。

2．マクロ浸襲経路

マクロ浸襲経路としての経口吸収、経皮吸収、腸管吸収、経気道吸収を始め、エラや粘膜を通じた吸収などについての蓋然性情報を収集することの重要性が明らかとなった。

3．生体内分布

生体内分泌について、脳血液関門などの臓器血液移行、経胎盤移行等の情報について、1．での範疇分類に応じて、情報収集を行なうことの重要性が明らかとなった。

4．細胞内機能移行

細胞生物学的な貪食、貪飲などを通じた細胞内浸襲後の細胞内小器官との相互作用について、情報を収集することの重要性が明らかとなった。

5．細胞表面分子との相互作用

細胞表面分子との相互作用、とくに抗原認識、抗体産生賦活、T細胞機能修飾蓋然性を検討することの重要性が明らかとなった。

E．結論

ナノ物質の生体影響は、生物学的な応用の展望と、生体の利得の側から見たときに好ましくない影響の発現する可能性が、表裏一体の関係にあり、従って、ナノマテリアル問題は、その表裏の関係に原点を置いて検討されることが必要である。

Summary

Mesp1 and Mesp2 are homologous basic helix-loop-helix (bHLH) transcription factors that are co-expressed in the anterior presomitic mesoderm (PSM) just prior to somite formation. Analysis of possible functional redundancy of Mesp1 and Mesp2 has been prevented by the early developmental arrest of Mesp1/Mesp2 double-null embryos. Here we performed chimera analysis, using either Mesp2-null cells or Mesp1/Mesp2 double-null cells, to clarify (1) possible functional redundancy and the relative contributions of both Mesp1 and Mesp2 to somitogenesis and (2) the level of cell autonomy of Mesp functions for several aspects of somitogenesis. Both Mesp2-null and Mesp1/Mesp2 double-null cells failed to form initial segment borders or to acquire rostral properties, confirming that the contribution of Mesp1 is minor during these events. By contrast, Mesp1/Mesp2 double-null cells contributed to neither epithelial somite nor dermomyotome formation, whereas Mesp2-null cells partially contributed to incomplete somites and the dermomyotome. This indicates that Mesp1 has a significant role in the epithelialization of somitic mesoderm. We found that the roles of the Mesp genes in epithelialization and in the establishment of rostral properties are cell autonomous. However, we also show that epithelial somite formation, with normal rostro-caudal patterning, by wild-type cells was severely disrupted by the presence of Mesp mutant cells, demonstrating non-cell autonomous effects and supporting our previous hypothesis that Mesp2 is responsible for the rostro-caudal patterning process itself in the anterior PSM, via cellular interaction.

Key words: Somitogenesis, Epithelial-mesenchymal conversion, Mesp2, Chimera analysis, Mouse

Introduction

Somitogenesis is not only an attractive example of metameric pattern formation but is also a good model system for the study of morphogenesis, particularly epithelial-mesenchymal interconversion in vertebrate embryos (Gossler and Hrabe de Angelis, 1997; Pourquié, 2001). The primitive streak, or tailbud mesenchyme, supplies the unsegmented paraxial mesoderm, known as presomitic mesoderm (PSM). Mesenchymal cells in the PSM undergo mesenchymal-epithelial conversion to form epithelial somites in a spatially and temporally coordinated manner. Somites then differentiate, in accordance with environmental cues from the surrounding tissues, into dorsal epithelial dermomyotome and ventral mesenchymal sclerotome (Borycki and Emerson, 2000; Fan and Tessier Lavigne, 1994). Hence, the series of events that occur during somitogenesis provide a valuable example of epithelial-mesenchymal conversion. The dermomyotome gives rise to both dermis and skeletal muscle, whereas the sclerotome forms cartilage and bone in both the vertebrae and the ribs. Each somite is subdivided into two compartments, the rostral (anterior) and caudal (posterior) halves. This rostro-caudal polarity appears to be established just prior to somite formation (Saga and Takeda, 2001).

Mesp1 and Mesp2 are closely related members of the basic helix-loop-helix (bHLH) family of transcription factors but share significant sequence homology only in their bHLH regions (Saga et al., 1996; Saga et al., 1997). During development of the mouse embryo, both *Mesp1* and *Mesp2* are specifically expressed in the early mesoderm just after gastrulation and in the paraxial mesoderm during somitogenesis. Mesp1/Mesp2 double-null embryos show defects in early mesodermal migration and thus fail to form most of the embryonic mesoderm, leading to developmental arrest (Kitajima et al., 2000). Mesp1-null embryos exhibit defects in single heart tube formation, due to a delay in mesodermal migration, but survive to the somitogenesis stage (Saga et al., 1999), suggesting that there is some functional redundancy, i.e. compensatory functions of Mesp2 in early mesoderm. During somitogenesis, both *Mesp1* and *Mesp2* are expressed in the anterior PSM just prior to somite formation. Although we have shown that Mesp2, but not Mesp1, is essential for somite formation and the rostro-caudal patterning of somites (Saga et al., 1997), a possible functional redundancy between Mesp1 and Mesp2 has not yet been clearly established.

To further clarify the contributions of Mesp1 and Mesp2 to somitogenesis, analysis of Mesp1/Mesp2 double-null embryos

is necessary, but because of the early mesodermal defects already described, these knockout embryos lack a paraxial mesoderm, which prevents any analysis of somitogenesis. We therefore adopted a strategy that utilized chimera analysis. As we have reported previously, the early embryonic lethality of a Mesp1/Mesp2 double knockout is rescued by the presence of wild-type cells in a chimeric embryo, but the double-null cells cannot contribute to the cardiac mesoderm (Kitajima et al., 2000). This analysis, however, focused only on early heart morphogenesis and did not investigate the behavior of Mesp1/Mesp2 double-null cells in somitogenesis. In this report, we focus upon somitogenesis and compare two types of chimeras using either Mesp1/Mesp2 double-null cells or Mesp2-null cells to investigate Mesp1 function during somitogenesis.

Another purpose of our chimera experiments was to elucidate the cell autonomy of Mesp functions. In the process of somite formation, mesenchymal cells in the PSM initially undergo epithelialization at the future segment boundary, independently of the already epithelialized dorsal or ventral margin of the PSM (Sato et al., 2002). Epithelial somite formation is disrupted in the Mesp2-null embryo, indicating that Mesp2 is required for epithelialization at the segment boundary. Although Mesp products are nuclear transcription factors and their primary functions must therefore be cell autonomous (transcriptional control of target genes), it is possible that the roles of Mesp2 in epithelialization are mediated by the non-cell autonomous effects of target genes. We therefore asked whether the defects in Mesp2-null cells during epithelialization could be rescued by the presence of surrounding wild-type cells. Additionally, we would expect to find that the role of Mesp2 in establishing rostro-caudal polarity is rescued in a similar way.

Our analysis suggests that Mesp1 and Mesp2 have redundant functions and are both cell-autonomously involved in the epithelialization of somitic mesoderm. In addition, our results highlight some non-cell autonomous effect of Mesp2-null and Mesp1/Mesp2-null cells.

Materials and methods

Generation of chimeric embryos

As described previously (Kitajima et al., 2000), chimeric embryos were generated by aggregating 8-cell embryos of wild-type mice (ICR) with those of mutant mice that were genetically marked with the *ROSA26* transgene (Zambrowicz et al., 1997). Mesp1/Mesp2 double-null embryos were generated by crossing *wko-del (+/–)* and *Mesp1(+/–)/Mesp2(+/cre)* mice as described previously (Kitajima et al., 2000). This strategy enables us to distinguish chimeric embryos derived from homozygous embryos, which have two different mutant alleles, from those derived from heterozygous embryos. Likewise, Mesp2-null embryos were generated by crossing *P2v1(+/–)* mice (Saga et al., 1997) and *P2GFP (+/gfp)* mice (Y.S. and S.K., unpublished) that were also labeled with the *ROSA26* locus. The genotype of the chimeric embryos was determined by PCR using yolk sac DNA.

Histology, histochemistry and gene expression analysis

The chimeric embryos were fixed at 11 days postcoitum (dpc) and stained in X-gal solution for the detection of β-galactosidase activity, as described previously (Saga et al., 1999). For histology, samples stained by X-gal were postfixed with 4% paraformaldehyde, dehydrated in an ethanol series, embedded in plastic resin (Technovit 8100, Heraeus Kulzer) and sectioned at 3 μm. The methods used for gene expression analysis by in-situ hybridization of whole-mount samples and frozen sections and skeletal preparation by Alcian Blue/Alizarin Red staining were described previously (Saga et al., 1997; Takahashi et al., 2000). Probes for in-situ hybridization for *Uncx4.1* (Mansouri et al., 1997; Neidhardt et al., 1997), *Delta-like 1 (Dll1)* (Bettenhausen et al., 1995) and *Paraxis* (Burgess et al., 1995) were kindly provided by Drs Peter Gruss, Achim Gossler and Alan Rawls, respectively. A probe for *EphA4* (Nieto et al., 1992) was cloned by PCR. For detection of actin filaments, frozen sections were stained with AlexaFluor 488-conjugated phalloidin (Molecular Probes) according to the manufacturer's protocol.

Results

Possible functional redundancy and different contributions of Mesp1 and Mesp2 in somitogenesis

During somitogenesis, both *Mesp1* and *Mesp2* are expressed in the anterior PSM just prior to somite formation and their expression domains overlap (Fig. 1A). Mesp1-null embryos form morphologically normal somites and show normal rostro-caudal patterning within each somite (Fig. 1B,E-H), indicating that Mesp1 is not essential for somitogenesis. By contrast, Mesp2 is essential for both the formation and rostro-caudal patterning of somites, as Mesp2-null embryos have no epithelial somites and lose rostral half properties, resulting in caudalization of the entire somitic mesoderm (Saga et al., 1997) (Fig. 1C,D).

Although somite formation and rostro-caudal patterning is disrupted in the Mesp2-null embryo, histological differentiation into dermomyotome and sclerotome is not affected. It is noteworthy that the Mesp2-null embryo still forms disorganized dermomyotomes without forming epithelial somites (Saga et al., 1997). As *Mesp1* is expressed at normal levels in the PSM of Mesp2-null embryos (Fig. 1C,D), it is possible that Mesp1 functions to rescue some aspects of somitogenesis in the Mesp2-null embryo. In order to further clarify the contributions of both Mesp1 and Mesp2 during somitogenesis, we therefore generated chimeric embryos with either Mesp2-null cells or Mesp1/Mesp2 double-null cells and compared the behavior of mutant cells during somitogenesis (Fig. 2).

Mesp2-null cells tend to be eliminated from the epithelial somite and the dermomyotome, but can partially contribute to both of these structures

We first generated Mesp2-null chimeric embryos (*Mesp2*$^{-/-}$ with *Rosa26*: wild) to analyze cell autonomy of Mesp2 function during somitogenesis. The control chimeric embryo (*Mesp2*$^{+/-}$ with *Rosa26*: wild) showed normal somitogenesis and a random distribution of X-gal stained cells (Fig. 3A). The Mesp2-null chimeric embryos formed abnormal somites that exhibited incomplete segmentation (Fig. 3B), but histological differentiation of dermomyotome and sclerotome was observed. Within the incomplete somite, X-gal-stained Mesp2-null cells were mainly localized in the rostral and central regions, surrounded by wild-type cells at the dorsal, ventral and caudal sides (Fig. 3B). The surrounding wild-type cells, however, did not form an integrated epithelial sheet, but consisted of several epithelial cell clusters. Such trends were more obviously observed in other sections, where wild-type cells were found to form multiple small epithelial clusters (Fig.

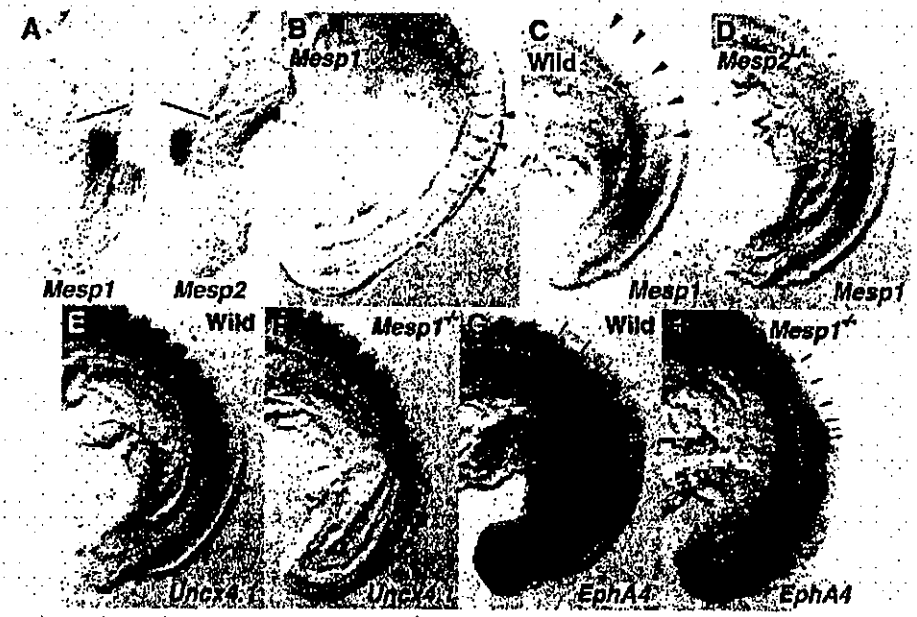

Fig. 1. *Mesp1* and *Mesp2* are co-expressed in the anterior PSM but have differing roles in somitogenesis. (A) Overlapping expression of *Mesp1* and *Mesp2* is revealed by in-situ hybridization using the left and right halves of the same embryo. The lines show most recently formed somite boundaries. (B-C) A Mesp1-null embryo (B) shows the same normal somite formation as a wild-type embryo (C). Arrowheads indicate somite boundaries. (D) In Mesp2-null embryos, no somite formation is observed but *Mesp1* is expressed at comparable levels to wild type, although its expression is anteriorly extended and blurred. (E-H) Mesp1-null embryos show normal rostro-caudal patterning of somites. (E,F) Expression of a caudal half marker, *Uncx4.1*. (G,H) Expression of a rostral half marker, *EphA4*. The lines indicate presumptive or formed somite boundaries and the dotted line indicates approximate position of somite half boundary.

3C,D). Mesp2-null cells tended to be eliminated from the epithelial clusters, although they were partially integrated into these structures (blue arrows in Fig. 3C,D). Likewise, small numbers of Mesp2-null cells were found to contribute to the dermomyotome (Fig. 3E,F). Mesp2-null cells also appeared to form the major part of the sclerotome.

Mesp2 is required for the cell-autonomous acquisition of rostral properties

We have previously demonstrated that suppression by Mesp2

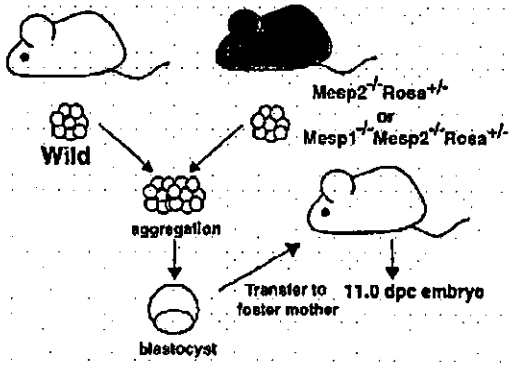

Fig. 2. Schematic representation of chimera analysis method. Either Mesp2-null or Mesp1/Mesp2 double-null embryos, genetically labeled with *Rosa* locus, were aggregated with wild-type embryos at the 8-cell stage, and the resulting chimeras were subjected to analysis at 11.0 dpc.

of the caudal genes *Dll1* and *Uncx4.1* in presumptive rostral half somites is a crucial event in the establishment of the rostro-caudal pattern of somites (Saga et al., 1997; Takahashi et al., 2000). As Mesp2-null embryos exhibit caudalization of somites, Mesp2-null cells are predicted to be unable to express rostral properties. Hence, Mesp2-null cells are expected to distribute to the caudal region of each somite where the rostro-caudal patterns are rescued by wild-type cells in a chimeric embryo. In this context, the localization of Mesp2-null cells at the rostral side was an unexpected finding. We interpret this to mean that the rostral location of Mesp2-null cells is due to a lack of epithelialization functions (see Discussion).

To examine rostro-caudal properties in Mesp2-null cells, located in the rostral side, we analyzed the expression of a caudal half marker gene, *Uncx4.1* (Mansouri et al., 1997; Neidhardt et al., 1997). Analysis of adjacent sections revealed that *lacZ*-expressing Mesp2-null cells, localized at the rostral and central portion, ectopically expressed *Uncx4.1* (Fig. 4A-D). This strongly suggests that Mesp2-null cells cannot acquire rostral properties even if surrounded by wild-type cells, and that Mesp2 function is cell-autonomously required for the acquisition of rostral properties. We also observed that the small number of Mesp2-null cells distributed mostly to the caudal end of the dermomyotome (Fig. 3E,F) and that the expression pattern of *Uncx4.1* was normal in the dermomyotome (Fig. 4E,F). In the sclerotome, *lacZ*-expressing Mesp2-null cells often distributed to the rostral side, where expression of *Uncx4.1* was abnormally elevated (Fig. 4G,H). The vertebrae of the Mesp2-null chimeric fetus showed a partial fusion of the neural arches, which was reminiscent of

Mesp2-hypomorphic fetuses (Fig. 4I,J) (Nomura-Kitabayashi et al., 2002). Fusion of proximal rib elements was also observed (Fig. 4K,L).

Mesp1/Mesp2 double-null cells cannot contribute to the formation of epithelial somites or to the dermomyotome

To address the question of whether Mesp1, in addition to Mesp2, exhibits any function during somitogenesis, we next generated Mesp1/Mesp2 double-null chimeric embryos and compared them with the Mesp2-null chimeric embryos described in the previous sections. We first performed whole-mount X-gal staining of embryos at 11 dpc. In the control chimeric embryo, the X-gal-stained Mesp1/Mesp2 double-heterozygous cells distributed randomly throughout the embryonic body, including the somite region (Fig. 5A,C). By contrast, the Mesp1/Mesp2 double-null chimeric embryo displayed a strikingly uneven pattern of cellular distribution in the somite region. The X-gal stained Mesp1/Mesp2 double-null cells were localized at the medial part of embryonic tail and were not observed in the lateral part of the somite region (Fig. 5B,D). Histological examination of parasagittal sections further revealed obvious differences in the cellular contribution to somite formation (Fig. 5E,F). In the control chimeric embryo, Mesp1/Mesp2 double-heterozygous cells distributed randomly throughout the different stages of somitogenesis (PSM, somite, dermomyotome and sclerotome: Fig. 5E). In the Mesp1/Mesp2 double-null chimeric embryo, neither the initial segment border nor epithelial somites were formed, but histologically distinguishable dermomyotome-like and sclerotome-like compartments were generated (Fig. 5F). In addition, Mesp1/Mesp2 double-null cells and wild-type cells were randomly mixed in the PSM, whereas the dermomyotome-like epithelium consisted exclusively of wild-type cells and the sclerotome-like compartment consisted mostly of Mesp1/Mesp2 double-null cells. This suggests that either Mesp1 or Mesp2 is cell-autonomously required for the formation of epithelial somite and dermomyotome. These results also indicate that PSM cells with different characteristics are rapidly sorted during somite formation.

Subsequent examination of transverse sections confirmed the elimination of Mesp1/Mesp2 double-null cells from dermomyotome (Fig. 5G,H). In the mature somite region, the wild-type dermomyotome-like epithelium was found to form the myotome (my) (Fig. 5I,J). Furthermore, the ventral part of this dermomyotome-like epithelium became mesenchymal and appeared to contribute to the dorsal sclerotome (dsc), implying that this initial dermomyotome-like epithelium actually corresponds to the epithelial somite exclusively composed of wild-type cells (Fig. 5I,J). Fluorescent phalloidin staining revealed that the apical localization of actin filaments is limited to the dorsal compartments, which are occupied by wild-type cells in the Mesp1/Mesp2 double-null chimeric embryo (Fig. 5K,L), indicating the Mesp1/Mesp2 double-null cells cannot undergo epithelialization.

It is known that the bHLH transcription factor paraxis (Tcf15 – Mouse Genome Informatics), is required for the epithelialization of somite and

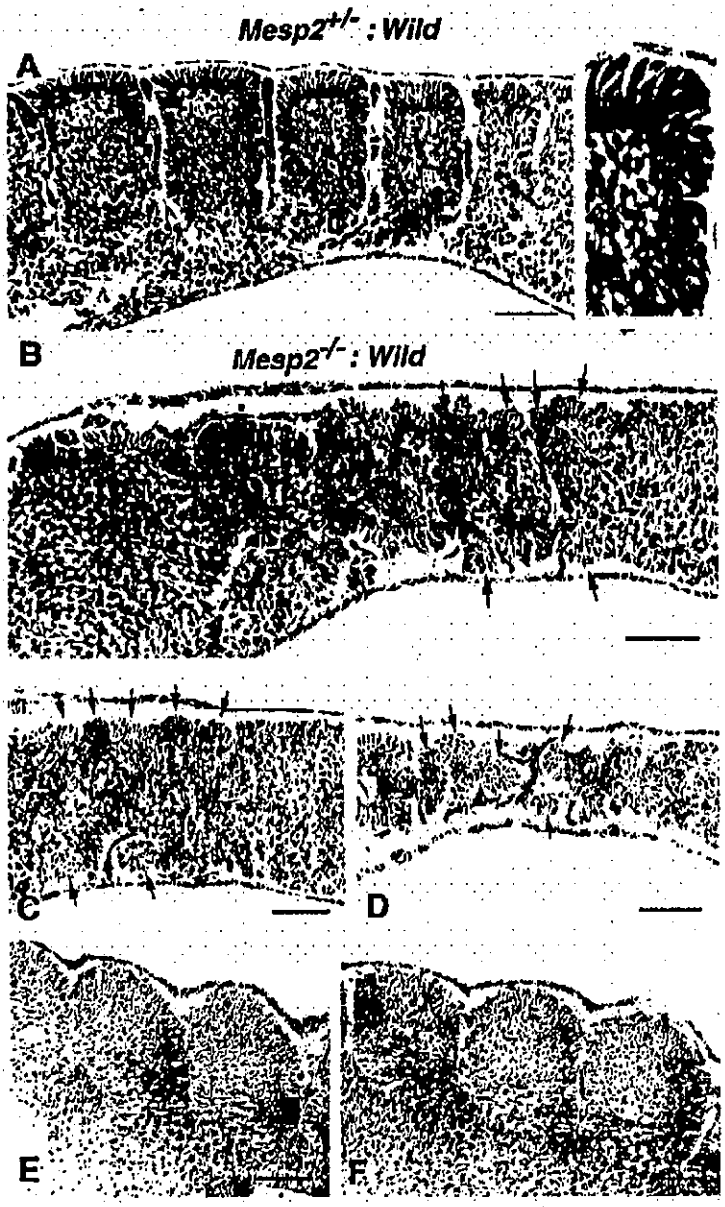

Fig. 3. Mesp2-null cells tend to be excluded from the epithelial region of the somites. (A) The control chimeric embryo undergoes normal somite formation and shows random distribution of labeled cells. The right panel is a high-power view of a somite. (B) In the Mesp2-null chimeric embryo, incompletely segmented somites are formed. Mesp2-null cells tend to be localized at the rostral and central region of these incomplete segments. Red arrows: wild-type cell clusters; blue arrows: Mesp2-null cell clusters. (C,D) Other sections indicating multiple small epithelial cell clusters (arrows). Note that Mesp2-null cells only partially contribute to the epithelial clusters (blue arrows). (E,F) A small number of Mesp2-null cells are distributed in the dermomyotome and are mostly localized at the caudal end. Scale bars: 100 μm.

dermomyotome (Burgess et al., 1995; Burgess et al., 1996). Although *Paraxis* expression is not affected in Mesp2-null embryos (data not shown), it is possible that it is influenced by the loss of both Mesp1 and Mesp2. We therefore examined the expression patterns of *Paraxis* in our Mesp1/Mesp2 double-null chimeras. In wild-type embryos *Paraxis* is initially expressed throughout the entire somite region (in both the prospective dermomyotomal and sclerotomal regions) in the anteriormost PSM and newly forming somites, and then localizes in the dermomyotomes (Burgess et al., 1995). The dorsal dermomyotomal epithelium, composed of wild-type cells, strongly expressed *Paraxis* in the chimeric embryo (Fig. 6A,B). In addition, adjacent sections revealed that *lacZ*-expressing Mesp1/Mesp2 double-null cells expressed *Paraxis* in the medial sclerotomal compartment (Fig. 6A,B, brackets). This suggests that *Paraxis* expression in the future sclerotomal region is independent of Mesp factors. However, at present we cannot exclude the possibility that the maintenance of *Paraxis* expression in the dermomyotome requires the functions of either Mesp1 or Mesp2.

Mesp1/Mesp2 double-null cells are incapable of acquiring rostral properties

To clarify the rostro-caudal properties of somites in our chimeric embryos, we examined the expression pattern of *Uncx4.1*. Control chimeric embryos exhibited a normal stripe pattern of *Uncx4.1* expression throughout the segmented somite region (Fig. 7A). By contrast, Mesp1/Mesp2 double-null chimeric embryos exhibited continuous *Uncx4.1* expression in the ventral sclerotomal region (Fig. 7B). This continuity was observed in the entire sclerotome-like compartment of the newly formed somite region and in the ventral sclerotome in the mature somite region. The caudal localization of *Uncx4.1* expression, however, was normal in the dermomyotome and the dorsal sclerotome, which consisted of wild-type cells (Fig. 5), even in Mesp1/Mesp2 double-null chimeras. This suggests that, like Mesp2-null cells, Mesp1/Mesp2 double-null cells are incapable of acquiring rostral properties. Since the mesoderm of Mesp1/Mesp2 double-null embryos lacks the expression of the major markers of paraxial mesoderm (Kitajima et al., 2000), and Mesp1/Mesp2 double-null cells do not exhibit histological features characteristic of epithelial somites in our current study, it is possible that Mesp1/Mesp2 double-null cells may lack paraxial mesoderm properties. However, the analysis of adjacent sections suggests that *lacZ*-expressing Mesp1/Mesp2 double-null cells themselves express *Uncx4.1*, a somite-specific marker (Fig. 7C,D), and they had also been found to have normal expression of *Paraxis* (Fig. 6A,B).

It is believed that the rostro-caudal pattern within somites and dermomyotomes is generated in the PSM and maintained in somites and dermomyotomes. We observed a normal rostro-caudal pattern in the dermomyotome (Fig. 7), although wild-type cells and Mesp1/Mesp2 double-null cells are mixed in the PSM (Fig. 5), of Mesp1/Mesp2 double-null chimeric embryos. As Mesp products are required for suppression of *Dll1* in the anterior PSM, a normal Dll1 stripe pattern cannot be formed if Mesp1/Mesp2 double-null cells are randomly distributed in

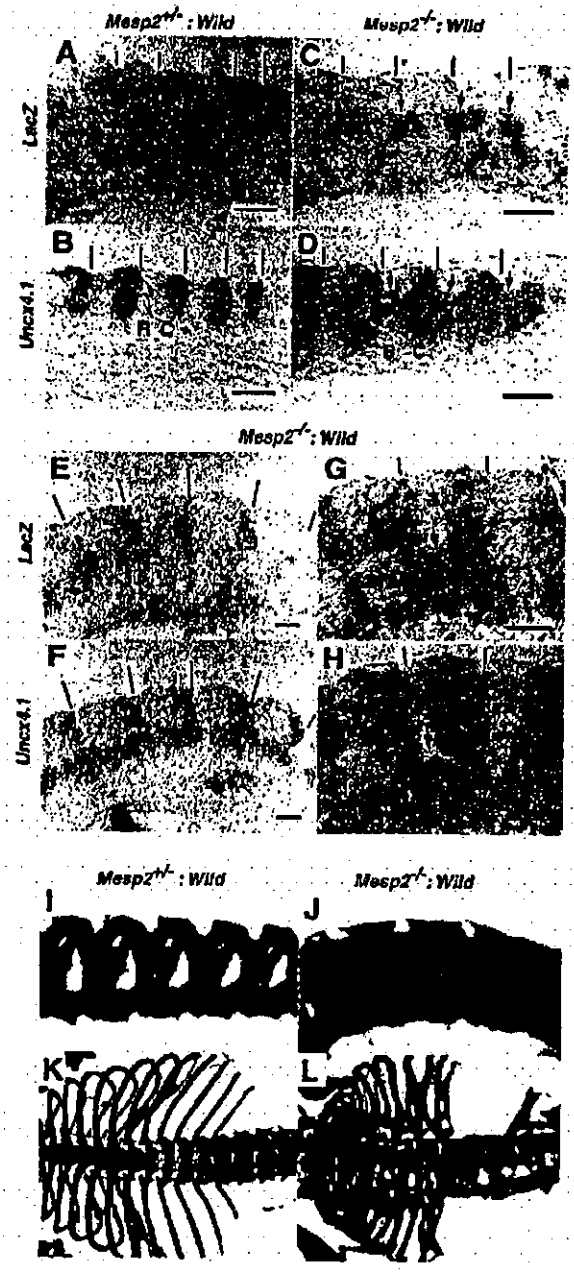

Fig. 4. Mesp2 function is cell autonomously required for rostral properties. (A-D) Expression of *lacZ* and *Uncx4.1* transcripts at the site of initial somite formation in control (A,B) and Mesp2-null (C,D) chimeric embryos. In the control, *lacZ*-expressing cells are randomly distributed and *Uncx4.1* expression is normal. In the Mesp2-null chimera, *lacZ*-expressing Mesp2-null cells at the rostral part of the incomplete segments (arrows in C) ectopically express *Uncx4.1* (arrows in D). Lines indicate somite boundaries. (E,F) In the dermomyotome, Mesp2-null cells are mostly localized at the caudal end, and the *Uncx4.1* expression pattern is normal. (G,H) In the sclerotome, the distribution of Mesp2-null cells results in expansion of *Uncx4.1* expression (arrows). (I) The control chimeric fetus shows normal vertebrae. (J) The Mesp2-null chimeric fetus exhibits partial fusion of the neural arches. (K) The control chimeric fetus shows normal ribs. (L) The Mesp2-null chimeric fetus shows proximal rib fusion. Scale bars: 100 μm. C, caudal compartment; R, rostral compartment.

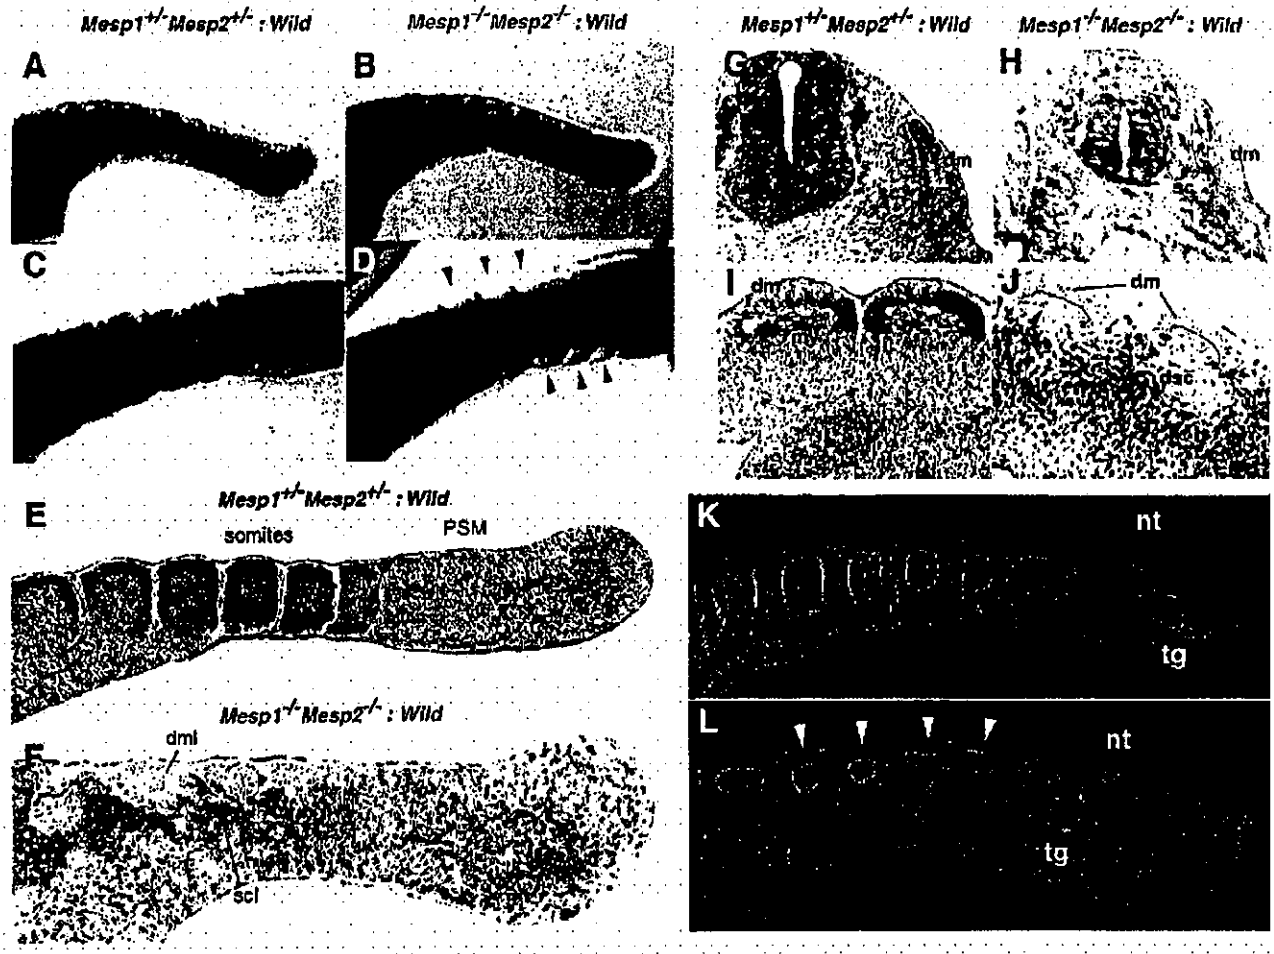

Fig. 5. Mesp1/Mesp2 double-null cells fail to contribute to epithelial somites or to the dermomyotome. (A-D) Tail regions from X-gal-stained whole-mount specimens of control (A,C) and double-null (B,D) chimeric embryos. (A,B) Lateral view. (C,D) Dorsal view. The blue double-heterozygous cells are randomly distributed in the control embryo, whereas the Mesp1/Mesp2 double-null cells are excluded from the lateral region of the somites (arrowheads in D). (E,F) Parasagittal sections of tails from chimeric embryos. (E) The labeled cells are randomly located in the control chimera. (F) The two types of cells are randomly mixed in the PSM, whereas the dermomyotome-like epithelium consisted exclusively of wild-type cells and the sclerotome-like compartment contained mostly Mesp1/Mesp2 double-null cells. Note that normal epithelial somites are not formed in this chimera. (G,H) Transverse sections show elimination of Mesp1/Mesp2 double-null cells from the dermomyotome. (I,J) The dermomyotome-like epithelium in the Mesp1/Mesp2 double-null chimeric embryo gives rise to dermomyotome, myotome (arrowhead in J) and the dorsal part of the sclerotome. Red arches indicate the inner surface of dermomyotome. (K,L) AlexaFluor 488-labeled phalloidin staining shows normal epithelialization of somites in the control chimera (K) and restriction of epithelialization in the dermomyotome-like compartment in the Mesp1/Mesp2 double-null chimera (L). dm, dermomyotome; dml, dermomyotome-like epithelium; dsc, dorsal part of the sclerotome; my, myotome; nt, neural tube; sc, sclerotome; scl, sclerotome-like compartment; tg, tail gut.

the anterior PSM. This is because 50% of cells cannot undergo suppression of Dll1 even in the future rostral half region. Therefore, our finding of a normal rostro-caudal pattern in the dermomyotome of double-null chimeras is surprising and raises the question of whether wild-type cells can be normally patterned in the presence of surrounding Mesp1/Mesp2 double-null cells. To determine how the rostro-caudal pattern in the dermomyotome is formed in the PSM, we examined the expression pattern of *Dll1* (Bettenhausen et al., 1995), the stripe expression profile of which is established in the anteriormost PSM via the function of Mesp2 (Takahashi et al., 2000). The *lacZ*-expressing Mesp1/Mesp2 double-null cells were subsequently found to be consistently localized in the sclerotome-like region, where *Dll1* expression was abnormally expanded (Fig. 6C,D). In the dermomyotome-like region, however, *Dll1* expression in the caudal half was normal. Intriguingly, strong *Dll1* expression in the anteriormost PSM was suppressed in a rostrally adjoining cell population, which is mainly occupied by wild-type cells (Fig. 6C,D, arrows). This implies that wild-type cells and Mesp1/Mesp2 double-null cells rapidly segregate at S–1 to S0, after which the rostro-caudal pattern of *Dll1* expression is formed in the partially segregated wild-type cell population but not in the randomly mixed cell population. In other words, the separation from Mesp1/Mesp2 double-null cells enabled normal rostro-caudal patterning of wild-type cells.

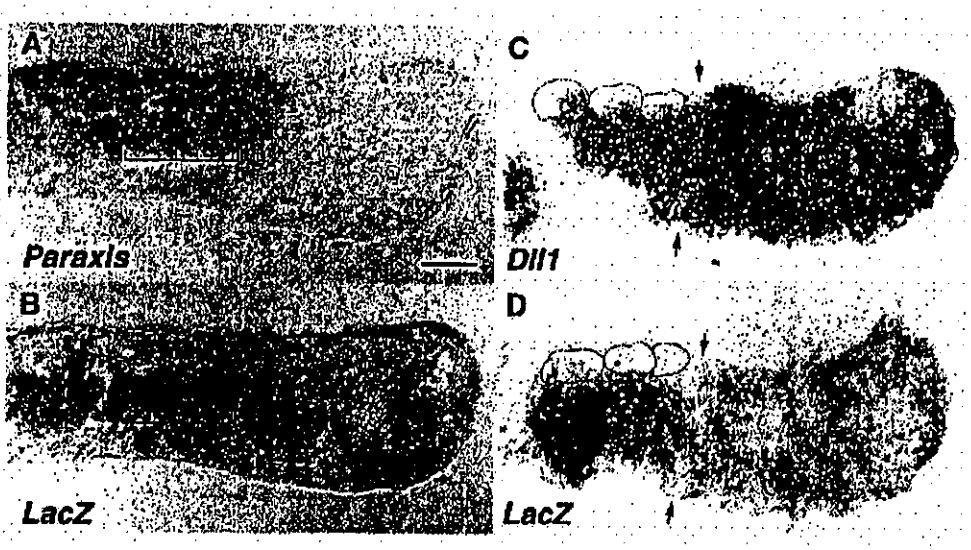

Fig. 6. (A,B) Mesp1/Mesp2 double-null cells express *Paraxis*. Adjacent parasagittal sections of the Mesp1/Mesp2 double-null chimeric embryo were stained for either *Paraxis* (A) or *lacZ* (B). Note that the expression domains of the two genes overlap in the medial sclerotomal region (brackets). (C,D) The rostro-caudal pattern in the dermomyotome is formed in a partially segregating wild-type cell population. Adjacent sections of the Mesp1/Mesp2 double-null chimeric embryos were stained for *Dll1* (C) or *lacZ* (D) mRNA. Red outlines demarcate the dorsal dermomyotome-like compartments. Note that suppression of *Dll1* expression occurs in a region mostly occupied by wild-type cells (arrows). Scale bar: 100 μm.

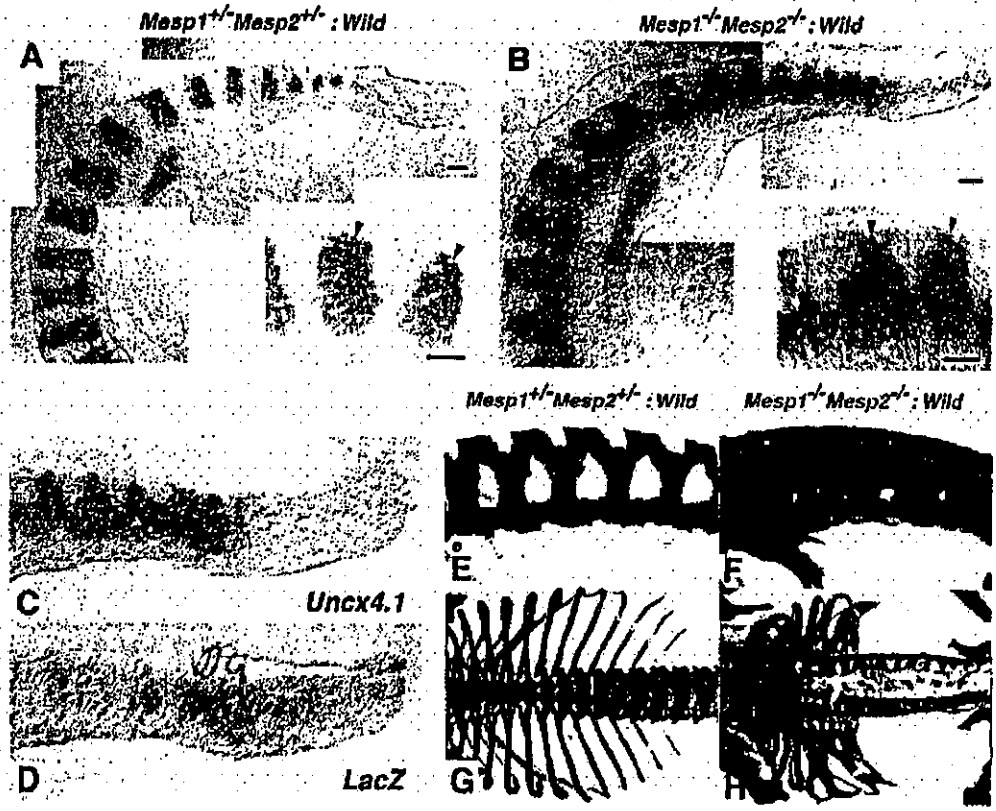

Fig. 7. Rostro-caudal patterning of the sclerotome is disrupted in Mesp1/Mesp2 double-null chimeric embryos. (A) The control chimeric embryos exhibit normal stripe patterns of *Uncx4.1* expression throughout the somite region. (B) The Mesp1/Mesp2 double-null chimeric embryos exhibit continuous *Uncx4.1* expression in the ventral sclerotomal region. Note that caudal localization of *Uncx4.1* expression is normal in the dermomyotome and dorsal sclerotome. The insets show a higher magnification of lumbar somites. (C,D) Adjacent sections showing that *lacZ*-expressing Mesp1/Mesp2 double-null cells express *Uncx4.1*. (E-H) The Mesp1/Mesp2 double-null chimeric fetus exhibits caudalization of the vertebrae and of the proximal ribs. (E) The control chimeric fetus shows normal metameric arrangement of the neural arches. (F) The Mesp1/Mesp2 double-null chimeric fetus shows severe fusion of the pedicles and the laminae of neural arches. (G) The control chimeric fetus has normal arrangement of ribs. (H) The double-null chimeric fetus shows severe fusion of the proximal elements of the ribs. Scale bars: 100 μm.

Mesp2-null fetuses display caudalized vertebrae with extensive fusion of the pedicles of neural arches and proximal elements of the ribs (Saga et al., 1997). The Mesp1/Mesp2 double-null chimeric fetuses also exhibited fusion of the pedicles of neural arches and the proximal ribs (Fig. 7E-H). Furthermore, the vertebrae of severe chimeric fetuses were indistinguishable from those of Mesp2-null fetuses. These observations indicate that Mesp1/Mesp2 double-null cells can differentiate into caudal sclerotome and possibly contribute to chondrogenesis.

Discussion

Mesp1 and Mesp2 not only exhibit similar expression patterns but also share common bHLH domains as transcription factors. Previous studies using gene replacement experiments (Saga, 1998) (Y.S. and S.K., unpublished) indicate that these genes can compensate for each other. However, the early lethality of double knockout mice hampered any further detailed analysis of somitogenesis. An obvious strategy to further elucidate the functions of Mesp1 and Mesp2 was, therefore, the generation of a conditional knockout allele for *Mesp2* in *Mesp1* disrupted cells in which the Cre gene is specifically activated in the paraxial mesoderm, which is now underway. Chimera analysis is also a powerful method as an alternative strategy. Comparisons of chimeras, composed of either Mesp2-null or Mesp1/Mesp2 double-null cells, made it possible to determine the contribution of Mesp1 to somitogenesis. Our results indicate that Mesp1 has redundant functions in the epithelialization of somitic mesoderm and additionally, by chimeric analysis, we were able to demonstrate the cell autonomy of Mesp1 and Mesp2 function during some critical steps of somitogenesis.

The relative contributions of Mesp1 and Mesp2 to somitogenesis

In Mesp1-null mice, epithelial somites with normal rostro-caudal polarity are generated, whereas Mesp2-null mice exhibit defects in both the generation of epithelial somites and the establishment of rostro-caudal polarity. Thus, it seems likely that Mesp2 function is both necessary and sufficient for somitogenesis. However, dermomyotome formation was observed, without normal segmentation, even in Mesp2-null mice. In view of the apparent redundant functions of Mesp1 and Mesp2 in somitogenesis, as demonstrated by our previous gene replacement study, it was possible that the Mesp1/Mesp2 double-null embryo would exhibit a much more severe phenotype in relation to somitogenesis. In our chimera analyses, both Mesp2-null and Mesp1/Mesp2 double-null cells exhibited complete caudalization of somitic mesoderm, indicating that Mesp1 function is not sufficient to rescue Mesp2 deficiency and restore rostro-caudal polarity. Likewise, both Mesp2-null and Mesp1/Mesp2 double-null cells were incapable of forming an initial segment boundary, showing that the contribution of Mesp1 is also minor during this process. By contrast, whereas Mesp1/Mesp2 double-null cells lacked any ability to epithelialize, Mesp2-null cells were occasionally integrated into epithelial somites and dermomyotome, indicating that the contribution of Mesp1 to epithelialization is significant and that Mesp1 can function in the absence of Mesp2 (Fig. 8). We therefore postulate that the epithelialization of dermomyotome, observed in Mesp2-null embryos, is dependent on Mesp1.

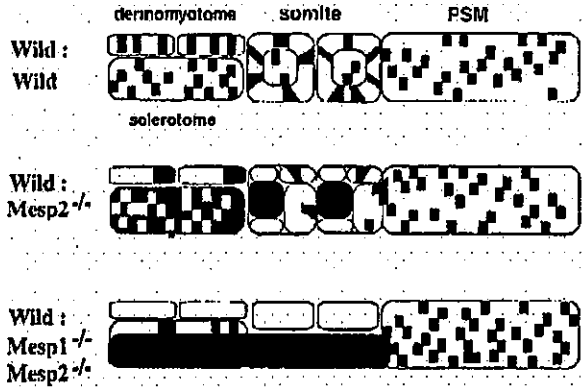

Fig. 8. A schematic summarization of the Mesp1/Mesp2 chimera experiments. Mesp1/Mesp2 double-null cells can contribute to neither epithelial somite nor dermomyotome formation, whereas Mesp2-null cells can partially contribute to both somites and dermomyotome. Red outlines indicate epithelialized tissues (epithelial somites, dermomyotomes and abnormal small clusters).

Mesp factors are cell autonomously required for epithelialization of somitic mesoderm but may also be non-cell autonomously required for morphological boundary formation

Conventional interpretations of the results of chimera analysis are generally based upon the regulative development of the vertebrate embryo and argue cell autonomy of specific gene functions in embryogenesis (Ciruna et al., 1997; Brown et al., 1999; Kitajima et al., 2000; Koizumi et al., 2001). Mesp1/Mesp2 double-null cells failed to form epithelial somites, even in the presence of surrounding wild-type cells. In addition, they were incapable of contributing to dermomyotome, where cell sorting occurs. This strongly suggests that Mesp factors are cell autonomously required for the epithelialization of somitic mesoderm. However, we also found striking non-cell autonomous effects of Mesp mutant cells on wild-type cell behaviors. That is, both types of Mesp mutant cell not only failed to undergo normal somitogenesis, but also inhibited the normal morphogenesis of wild-type cells. This implies that there are non-cell autonomous roles for Mesp factors in the establishment of the future somite boundary, as we will discuss further.

Initial epithelial somite formation is achieved by the mesenchymal-epithelial transition of cells located in the anterior PSM. A future somite boundary is established at a specific position in the PSM, followed by gap formation between the mesenchymal cell populations. Subsequently, cells located anterior to the boundary are epithelialized. This process is known to be mediated by an inductive signal from cells posterior to the boundary (Sato et al., 2002). Therefore, defects in epithelial somite formation can be explained in two principal ways: a lack of cellular ability to epithelialize (cell autonomous) and a lack of an inducing signal, which is produced in the anterior PSM by a mechanism mediated by Notch signaling (thus non-cell autonomous). In the case of chimeras of Mesp1/Mesp2 double-null cells, no local

boundary formed by locally distributed wild-type cells was observed, i.e. even a gap between wild-type cells was never observed in the mixture of Mesp1/Mesp2 double-null cells and wild-type cells. It is likely, therefore, that the wild-type cell population can form a boundary only after separation from Mesp1/Mesp2 double-null cells (Fig. 8). By contrast, some local boundaries between epithelial wild-type cell clusters were occasionally observed in chimeras with Mesp2-null cells. Considering that there is functional redundancy between these transcription factors, it is possible that either Mesp1 or Mesp2 is necessary for the formation of a signaling center or source of the putative inductive signal. Hence, we cannot exclude the possibility that the lack of Mesp function may affect non-cell autonomous generation of the inductive signal in the anterior PSM.

Formation of epithelial somites requires paraxis, which is a transcription factor (Burgess et al., 1996; Nakaya et al., 2004). We observed that Mesp1/Mesp2 double-null cells at the medial sclerotomal region expressed *Paraxis*, indicating that Mesp factors are not absolutely required for *Paraxis* expression. Defects in epithelial somite formation in paraxis-null embryos, with normal *Mesp2* expression (Johnson et al., 2001), and in Mesp2-null embryos, with normal *Paraxis* expression, imply that epithelial somite formation independently requires both gene functions.

Mesp2 is cell autonomously required for the acquisition of rostral properties

The distribution of Mesp2-null cells in the Mesp2-null chimeric embryos may appear somewhat paradoxical, as they are localized at the rostral side in the incomplete somites but at the caudal side in the dermomyotome. Initial localization at the rostral and central region, however, is likely to be due to the relative lack of epithelialization functions. In mammalian and avian embryos, mesenchymal-to-epithelial conversion of the PSM commences from the rostral side of the future somite boundary, i.e. the caudal margin of the presumptive somite (Duband et al., 1987). Epithelialization then proceeds anteriorly in the dorsal and ventral faces and in such a process, Mesp2-null cells, which are less able to participate in epithelialization, may therefore be pushed to the central and rostral sides. Thus, the majority of the Mesp2-null cells localize to the central, prospective sclerotomal region and a small number of them are integrated in the future dermomyotomal region. The incomplete somites then undergo reorganization into dermomyotome and sclerotome, and small numbers of Mesp2-null cells in the dermomyotome may be sorted out to the caudal end. Therefore, the apparently complex distribution pattern of Mesp2-null cells is likely to reflect a combination of defects in epithelialization and rostro-caudal patterning. In the incomplete segments of Mesp2-null chimeric embryos, the Mesp2-null cells fail to acquire rostral properties even when localized at the rostral side. Moreover, in the dermomyotome, where rostro-caudal patterning is rescued, Mesp2-null cells are mostly localized in the caudal region. These observations suggested that the requirement of Mesp2 for the acquisition of rostral properties is cell autonomous. Similarly, it has been reported that presenilin 1 (Psen1) is required for acquisition of caudal half properties (Takahashi et al., 2000; Koizumi et al., 2001) and that Psen1-null cells cannot contribute to the caudal half of somites in chimeric embryos, showing cell autonomous roles for Psen1 (Koizumi et al., 2001).

Mesp mutant cells affect the rostro-caudal patterning of somites due to the lack of cellular interaction with wild-type cells

In a previous study, we have shown that the rostro-caudal patterning of somites is generated by complex cellular interactions involved in positive and negative feedback pathways of Dll1-Notch and Dll3-Notch signaling, and regulation by Mesp2 in the PSM (Takahashi et al., 2003). In chimeras with either Mesp2-null or Mesp1/Mesp2 double-null cells, the mutant cells were distributed evenly and did not show any sorting bias in a rostro-caudal direction in the PSM. Since both Mesp2-null and Mesp1/Mesp2 double-null cells have the ability to form caudal cells, it is likely that if wild-type cells could occupy the rostral part of future somite regions and have the ability to sort in the PSM, a normal rostro-caudal patterning would be generated. We did not observe this, however, and conclude that the presence of mutant cells lacking Mesp factors must have disrupted normal cellular interactions via Notch signaling. Thus these non-cell-autonomous effects of our mutant cells are strongly supportive of our previous contention that rostro-caudal pattering is generated by cellular interactions via Notch signaling.

4. トキシコゲノミクス

菅野 純　相崎健一　五十嵐勝秀　小野 敦　中津則之

遺伝子発現カスケード解析を目指した形質非依存型トキシコゲノミクスに適用するため，マイクロアレイから細胞1個当たりのmRNA絶対量を得る方法（"Percellome"）を開発した．これにより遺伝子発現量を，ゼロを起点とする均等目盛りで表示し直接比較することができるようになった．対照群も処置群も無理なく同列に表示することができ，さらなる標準化操作が原則的に不必要となったため，測定し得たすべての遺伝子についてマイクロアレイ間はもとより，実験間での直接比較が行えるようになった．この特長は，生物学者が内容を直感的に把握しやすいようなデータの可視化にも役立ち，その後のデータ解析とインフォマティクス形成を促進することが示されつつある．本システムは大型プロジェクトを対象として開発したものであるが，実際には小規模の実験サンプルに対しても有用性が高いことが実証されている．特に変動遺伝子リストの遺伝子数が飛躍的に増大することが多い．それは，変動比率による足切りやハズレ値計算のような統計手法を用いる必要がなく，個々の遺伝子について逐一比較検討ができるためである．異なったプラットフォーム間でのデータ互換にも拡張可能であり，研究規模やプラットフォームの種類にかかわらずデータをもちより，相互にデータを直接比較することが可能なコンソーシアムを構築することに本手法が貢献することが期待される．

はじめに

毒性学は，生物界（biosphere）と化学物質界（chemosphere）との相互作用を解析し，現実に起きてしまった有害作用（薬の副作用，健康被害など）の把握，評価，対策のみならず，そのような事態の未然防止を目指す学問体系である．例えば，PCB（ポリ塩化ビフェニール）はその電気抵抗性，熱安定性，低反応性などから，工業的に優秀な材料として熱交換や絶縁に汎用された．この物質の毒性知識が早期に浸透していれば食品を直接加熱する熱媒体にPCBを用いるという発想は回避されたのかもしれない．当時の生物学・臨床医学・病理学・毒性学では，PCBのような化学物質の生体影響は，肝臓などでの代謝酵素（P450など）の誘導現象として把握されていたが，その基礎となるリガンド依存的転写因子群（AhR, CAR, PXRをはじめとするorphan受容体群）とその関連シグナル伝達に関する事象が明らかとなってきたのは比較的最近のことである[1]．その結果を受けて胎児影響を含む毒性の分子機構が明らかになるに連れて，実際にどの程度の暴露が，どの発達時期の人体に，どのように有害であるかの判断がより正確にくだせるようになり
