

suggest that the positive charge of the vector complexes is not always an essential factor for gene transfection.

From the viewpoint of transfection efficiency under physiological conditions, the PIC micelles showed excellent characteristics compared to the other vectors.

Fig. 11. Influence of preincubation with serum on transfection efficiency. Transfection was performed to 293 cells by PIC micelles (12-48, $r = 2.0$), PLL/pDNA complexes (Plys-polyplex: $r = 2.0$), and lipoplex (LipofectAMINETM/pDNA complex). The preincubation procedure of these complexes was done in 20% serum for 30 min prior to transfection ($n = 4$, \pm S.D.).

The PIC micelles retained a sufficient transfection efficiency toward cultured cells even after preincubation with 20% serum for 30 min, which is in sharp contrast to the lipoplex showing a drastic decrease in the efficiency after serum preincubation (Fig. 11). To get insight into the mechanism of the serum effect, the cellular association of fluorescein-labeled pDNA in these complexes was then evaluated by flow cytometry. As shown in Fig. 12, considerable association was obtained in each complex in the absence of serum. Even after the preincubation with 20% serum, the histogram for the cells treated with the PIC micelle system showed a minimal change compared to that obtained in the absence of serum, being consistent with the stability of the PIC micelles in the serum-containing environment [19]. However, the cellular association of pDNA became heterogeneous for the system of lipoplex and PLys-polyplex pretreated with serum, and eventually, there appears a considerable cellular fraction with a low fluorescence intensity, indicating a reduced pDNA association. These results are in line with a steep reduction in the transfection efficiency of the lipoplex and PLys-polyplex system after preincubation with serum.

A decrease in the transfection efficiency in the presence of serum has been inevitable for most of the non-viral vectors [38–41]. The obstructive effect of serum may be partly due to the non-specific interaction of the vector complexes with proteinous components,

Fig. 12. Influence of preincubation with serum on cellular association of fluorescein-labeled pDNA. PIC micelles (12-48, $r = 2.0$), PLL/pDNA complexes (Plys-polyplex: $r = 2.0$), and lipoplex (LipofectAMINETM/pDNA complex) formed with fluorescein-labeled pDNA were applied to 293 cells. Upper figures: cyto-fluorogram in the absence of serum; lower figures: after preincubation of the complexes with 20% serum for 30 min.

which induces the decrease in the cellular uptake and gene expression [42]. From this point of view, the serum-tolerable property of the PIC micelle system is quite promising. Furthermore, ligand molecules may be installed on the surface of the micelles using the functionality of the PEG distal end, allowing the micelle system to have a cellular specific interaction through a receptor-mediated mechanism [43]. The major obstacle of the present micellar system is a requirement of an endosome-disrupting reagent, such as chloroquine, to achieve sufficient gene expression. This may be overcome by modifying the polycation segment to have a buffering property, expecting the so-called proton-sponge effect proposed by Behr et al. [6]. Indeed, the synthesis of novel block copolymers having a polycation segment with a lowered pKa, including poly(ethylenimine) [44] and poly(*N,N*-dimethylaminoethyl methacrylate) [45], has recently been accomplished, and their use in a PIC micelle assembly with pDNA is now underway in our laboratory.

In particular, the 12-48/pDNA ($r = 2.0$) micelle achieved the highest gene expression in this study. It contains a single molecule of pDNA in the core with effective charge-shielding by the dense PEG corona around the complex. It is worth noting that PIC micelles have a small size comparable to a virus of approximately 80 nm, being advantageous to attain a smooth tissue permeability as well as high cellular association. Ligand molecules are even able to be attached to the distal chain end of the PEG corona for targeting a specific receptor, mimicking the spike protein of natural viruses. In this regard, a virus-inspired design of the PIC micellar vector is of interest. Indeed, intracellular trafficking of a virus, including the pH-triggered endosomal escape as well as nucleus transport, may be mimicked in the micellar system using a polycation segment possessing the proton sponge effect as poly(ethylenimine) and poly(dimethylaminoethyl methacrylate) as well as by the installation of a nuclear transport signal. Research in this direction is now in progress in our laboratory, and the results may be published in a forthcoming paper.

5'-TGGTAGCTGGTACTTCTAATGC-3' and 5'-CATAAG-GTCCGGAGTAGTTCTC-3' for AR-1; and 5'-CAGAAG-TATCTATGTGCCAG-3' and 5'-ATCTTCTGGGATGGGTC-CTCAG-3' for AR-2. Up to 35 cycles of amplification were performed, with each cycle consisting of 96°C for 30 s, 55°C for 60 s, and 72°C for 60 s.

Analysis of Skeletal Morphology. Bone radiographs of excised femora and tibiae from 8-week-old WT and ARKO littermates were taken by using a soft x-ray apparatus (CMB-2; Softex, Tokyo). Three-dimensional computed tomography scanning was performed by using a composite x-ray analyzing system (NX-HCP; NS-ELEX, Tokyo). Bone mineral density (BMD) was measured by dual energy x-ray absorptiometry using a bone mineral analyzer (Piximus densitometer; Lunar, Madison, WI). Skeletal preparations for morphology were performed as described (15). Trabecular bone parameters were measured in an area 1.2 mm in length from 0.1 mm below the growth plate at the proximal metaphysis of tibiae, and cortex bone parameters were measured at the midshaft of femora.

Orchidectomy and Hormone Replacement. Male WT and ARKO littermates were orchidectomized or sham operated at 3 weeks of age and implanted s.c. with a slow-releasing pellet (10 mg/60 days) (Innovative Research of America) of placebo, testosterone (T), or 5 α -dehydrotestosterone (DHT). BMD of femora was compared among eight experimental groups at 8 weeks of age.

Measurement of Serum Bone Metabolic Markers. Serum osteocalcin and urinary deoxyypyridinoline were measured as bone formation and resorption markers in male WT and ARKO mice. Blood was sampled at time of death, and urine was collected for 24 h before death by using oil-sealed bottles in metabolic cages (Kurea, Tokyo). Concentration of deoxyypyridinoline was corrected according to urinary creatinine concentration.

Statistical Analysis. Group means were compared by ANOVA, and the significance of differences were determined by post hoc testing with Bonferroni's method.

Ex Vivo Osteoblast Cultures. Osteoblast cultures were performed as described (15). For the cell proliferation assay, primary osteoblasts were inoculated at a density of 2×10^3 cells per well in a 96-multiwell plate for 2 days, and cell number was counted with cell-counting kit solution (Wako Pure Chemical) according to the manufacturer's protocol. For the measurement of alkaline phosphatase activity, primary osteoblasts were inoculated at a density of 5×10^4 cells per 24 multiwells and cultured in α MEM containing 10% FBS and 50 μ g/ml ascorbic acid. After 14 days of culture, alkaline phosphatase activity in the cell lysate was measured by using a Wako ALP kit (Wako Pure Chemical).

Osteoclastogenesis in Coculture of Bone Marrow Cells and Osteoblasts. To visualize osteoclasts, staining for tartrate-resistant acid phosphatase (TRAP) activity is widely used (15). TRAP-positive multinucleated osteoclasts were generated from hemopoietic cells by coculturing with osteoblasts. As a source of hemopoietic cells, bone marrow cells (5×10^5 cells per well) and osteoblasts (5×10^4 cells per well) were isolated and placed in 0.5 ml per 24 multiwells of α MEM/10% FBS for 8 days in the presence of 10 nM 1 α ,25(OH) $_2$ D $_3$ (16). To determine osteoclast survival, osteoclasts were isolated and cultured as described (15). The number of TRAP-positive and trypan blue-negative multinucleated cells were counted at 0, 12, 18, 24, and 48 h. Bone resorption activity was measured as described (15).

Osteoclastogenesis in Bone Marrow Cell Culture. Bone marrow cells were inoculated at a density of 5×10^5 cells per 24 multiwells and

cultured in 1.0 ml per 24 multiwells of α MEM/10% FBS with 100 ng/ml macrophage colony-stimulating factor (M-CSF) for the first 48 h, after which 100 ng/ml M-CSF and 100 ng/ml RANKL were added and incubated for an additional 96 h. TRAP-positive multinucleated osteoclasts were then counted.

RT-PCR Analysis of RANKL Gene Expression. Semiquantitative RT-PCR was carried out on primary cultured osteoblasts for a number of osteoblastic factor genes (17). After osteoblasts were cultured to confluency in α MEM containing 10% FBS, 1 α ,25(OH) $_2$ D $_3$ (10 nM) was added with DHT (10 nM) or vehicle and cultured for 48 h. Total RNA extraction and reverse transcription was performed as described above. After first-strand cDNA synthesis, 5% of the reaction mixture was amplified with *r-Taq* DNA polymerase (Takara Shuzo) by using specific primer pairs 5'-GCATCGCTCTGTTCCCTGTA-3' and 5'-GTGCTCCCTCCTTTTCATCA-3' for RANKL and G3PDH. Up to 25 cycles of amplification were performed, with each cycle consisting of 96°C for 30 s, 55°C for 60 s, and 72°C for 60 s.

Results

Male ARKO Mice Exhibit Abnormalities Typical of Testicular Feminization Mutant Rodents. To avoid male infertility caused by AR mutation, thereby preventing the establishment of a line of AR-deficient mice, we applied the Cre-loxP system to first flox the *AR* gene on the sole X chromosome in male mice (14). Floxed male mice (AR^{L3/Y}) (Fig. 1a) seemed completely normal with regard to bone mass and reproduction and showed no apparent differences from WT littermates. Male ARKO (AR^{L-/Y}) mice, descended from female AR heterozygotes (AR^{+L/-}), showed growth retardation compared with male littermates, but growth curves and external reproductive organs were indistinguishable from those of female littermates up to 8 weeks of age (Fig. 1b). Reflecting the atrophic testis in 8-week-old AR^{L-/Y} mice, testicular androgen production seemed to be severely impaired, leading to marked reduction in serum gonadal androgen levels, whereas serum estrogen and adrenal androgen levels remained unchanged (Fig. 1c). Thus, the phenotypic abnormality of AR^{L-/Y} mice seemed identical to that reported for testicular feminization mutant rodents, natural mutants with AR dysfunction (3, 10). To our surprise, female ARKO (AR^{L-/L-}), which never exist in nature, exhibited no phenotypic abnormality up to 8 weeks of age. However, it was possible that the abnormal AR protein derived from the genetically mutated AR gene locus still retained some level of androgen responsiveness (18). To address this issue, the presence of AR transcripts in bone in both male (AR^{L-/Y}) and female (AR^{L-/L-}) ARKO mice was assessed. No transcripts were detected by Northern blotting (data not shown) or by RT-PCR using several primer pairs performed on total bone tissue (Fig. 1d). These findings established that our ARKO mouse was indeed a mammalian AR-null mutant model.

Osteopenia in Male ARKO Mice. To examine the physiological roles of AR in mediating androgenic effects on bone tissue, we first analyzed the skeletal morphology of AR^{L-/Y} mice. Soft x-ray analysis revealed severe osteopenia of femora and tibiae from 8-week-old male mice (Fig. 1e), but also that bone shape and bone length (Figs. 1e and 2b) were not affected by AR inactivation. This was consistent with the clear loss in radiographic BMD of femora from AR^{L-/Y} mice compared with WT male littermates. The BMD of AR^{L-/Y} mice was even lower than that of WT female littermates (Fig. 2a). Three-dimensional computed tomography scan analysis of femora showed that bone loss in AR^{L-/Y} mice occurred throughout the entire femur (Fig. 2c). Histomorphometric analysis of proximal tibiae from AR^{L-/Y} mice confirmed that trabecular bone volumes (bone volume per tissue volume: BV/TV) were markedly decreased, whereas no overt differences in growth plates were detected between

Fig. 1. (a) Strategy to generate male and female ARKO mice using CMV-Cre transgenic mice. (b) Growth curves of ARKO and WT littermate mice. (c) Serum hormone levels in 8-week-old ARKO and WT mice. (d) Lack of AR expression in bone of ARKO mice (RT-PCR). (e) Soft x-ray images of femora and tibiae from 8-week-old ARKO and WT mice.

AR^{L-Y} and WT mice (Fig. 2d). Such bone loss was also evident in cortical bones as estimated by cortex thickness (Fig. 2e). In contrast, no clear loss of bone mass was detected in female ARKO mice (Figs. 1e and 2a). Together, these findings suggest that AR^{L-Y} mice developed osteopenia, which implies that the AR function is required for male-type bone mass and remodeling.

The Suppressive Function of AR in Bone Resorption Is Abrogated in Male ARKO Mice. To further study the process of bone loss in AR^{L-Y} mice, bone remodeling was assessed. The bone formation rate of the trabecular bone was directly estimated by calcein double-labeling of the mineralized matrix (17). Unexpectedly, the bone formation parameters (Ob.S/BS and MAR) were significantly increased in AR^{L-Y} mice, with increased thickness of the region between the two calcein-labeled layers compared with WT littermates (Fig. 3a). This increased bone formation was also found in the cortical bone, in the endocortical area of the axial section (Fig. 3b). We observed an increase in the number of TRAP-positive mature osteoclasts (Fig. 3c). This was reflected in the significantly increased bone resorption parameters (Oc.S/BS, N.Oc/B.Pm) (Fig. 3c). Our finding of enhanced bone turnover was further supported by the increased levels of serum osteocalcin and urinary deoxypyridinoline (Fig. 3d). Although female ARKO mice exhibited no abnormal bone

remodeling, our findings suggested that AR inactivation caused high turnover bone remodeling with higher bone resorption than formation, resulting in the development of osteopenia in males.

Effects of Androgens Other Than Those from Locally Converted Estrogen on Male Bone Remodeling. It is thought that estrogen converted from serum testosterone by aromatase expressed in androgen target tissues, including bone, contributes to apparent androgen activity (6). As serum testosterone levels were drastically decreased due to atrophic testes in AR^{L-Y} mice, it was impossible to exclude the possibility that the osteopenia in AR^{L-Y} mice simply reflected the impaired action of converted estrogen from serum testosterone on skeletal tissues. To address this issue, aromatizable testosterone (T) and nonaromatizable androgen DHT were given to orchidectomized AR^{L-Y} and WT littermates, and the femur BMD was assessed. Whereas orchidectomy caused no further BMD loss in AR^{L-Y} femora, BMD values from orchidectomized WT littermates were higher, but not significantly, than those of AR^{L-Y} mice (Fig. 3e). Also, whereas T, but not DHT, effectively recovered BMD, the recovery in AR^{L-Y} mice due to T was only $\approx 50\%$ of that in intact males (Fig. 3e), which suggests that androgen actions mediated via AR are significant in protecting against bone loss.

Suppressive Effects of AR on *in Vitro* Osteoclastogenesis and RANKL Gene Expression in Osteoblasts. To further explore the mechanisms of increased bone resorption in AR^{L-Y} mice, *in vitro* osteoclas-

Fig. 4. (a) Osteoclastogenesis in bone marrow cell and osteoblast cocultures. Discussion

The present study, using orchidectomized ARKO mice, directly demonstrates that AR function is essential for androgen effects on the male skeleton. Although a number of previous studies have assessed the bone phenotypes of testicular feminization mutant rodents and humans eventually treated with sex hormones (3, 5), it has still been difficult to isolate AR functions in the skeletal system due to the local conversion of androgens to estrogens (6). When aromatizable testosterone (Fig. 3e) was given to orchidectomized ARKO mice, bone loss was only partially prevented, clearly establishing the pivotal function of AR in male-type bone remodeling. This finding is supported by previous reports concerning the beneficial effects of testosterone in male $\text{ER}\alpha^{-/-}$ and $\text{ER}\alpha\beta^{-/-}$ bone (22). As no clear bone loss in female ARKO mice was detected, AR is likely to be one of the determining factors in the formation of male-type bone, along with other AR downstream factors that may be encoded in male-specific Y chromosome regions. However, as bone loss was also induced by inactivation of either $\text{ER}\alpha$ or aromatase in male mice (23, 24), ER-mediated estrogen signaling also seems to be physiologically significant in the retention of male-type bone mass and bone remodeling. In such mice, high bone turnover with increased bone resorption was also observed. Therefore, it is possible that receptor-mediated signaling by both androgens and estrogens is convergent in the suppressive action on male bone resorption.

Unlike male ARKO mice, no overt differences in bone phenotype and mass were found between female AR-deficient

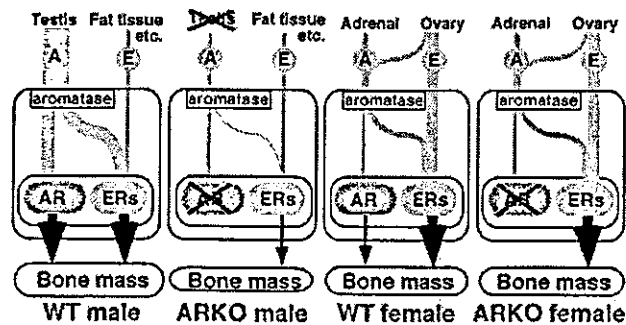

Fig. 5. Schema of skeletal sex hormone action. In male WT mice, skeletal sex hormone activities are mediated by both AR and ER. In female WT mice, skeletal function of ER is likely to dominate over that of AR as serum levels of AR ligands in females are quite low. In male ARKO mice, testicular testosterone production is severely impaired by hypoplasia of the testes, leading to a lack of skeletal sex hormone actions. In contrast, female ARKO mice may not be greatly affected by disruption of AR signaling.

and WT littermate mice at 8 weeks of age. Although the effects of anabolic androgens on bone have been documented in female rodents and humans, the physiological function of AR may not be significant because of the probably dominant role of ER function in female bones (Fig. 5), reflecting the high levels of serum estrogens in females. However, under certain conditions, such as estrogen deficiency in postmenopausal women (4), AR-mediated androgen effects may become physiologically significant in the protection against bone loss. This hypothesis will be tested using ovariectomized female ARKO mice in future studies.

The higher rate of bone resorption than formation with increased osteoclastogenesis observed in the $\text{AR}^{\text{L-Y}}$ mice has been implied in previous reports (3, 5, 25). However, several recent reports (19, 26, 27) were inconsistent with our findings that osteoclast precursor cells were unaffected by AR deficiency in terms of cell survival and responsiveness to well characterized osteoclastogenesis inducers such as $1\alpha,25(\text{OH})_2\text{D}_3$ and M-CSF (Fig. 4 a-d). Similar to AR, critical $\text{ER}\alpha$ functions in osteoclast precursor cells from $\text{ER}\alpha^{-/-}$ mice were not detected during *in vitro* osteoclastogenesis, and increased expression of the *RANKL* gene in osteoblast was also found (unpublished results). Together with previous findings of suppressive $\text{ER}\alpha$ effects on *RANKL* signaling (28), we speculate that the convergent functions of AR and $\text{ER}\alpha$ in male bone formation and remodeling are mediated through their suppressive functions on *RANKL* gene expression in osteoblasts. To test this hypothesis, identification of the negatively regulatory elements by receptors in the *RANKL* gene promoter (29) is clearly required.

We thank Dr. Yoshiaki Azuma and the hard tissue research team at Kureha Chemical for technical assistance and Dr. Toru Akune for helpful discussion. Object. The purpose of this study was to evaluate the advantages of using an image guidance system to aid in the resection of ossified of the ligamentum flavum (OLF) in the thoracic spine. The procedure and surgery-related outcome are discussed.

Methods. Ten patients with myelopathy underwent laminotomy with medial facetectomy and an image guidance system was used to remove the OLF. No neurological deterioration occurred, and postoperative computerized tomography scanning demonstrated successful decompression and good preservation of the lateral parts of the facet joints.

Conclusions. The image guidance system allows accurate resection of the OLF while preserving as much as possible the facet joints and posterior elements of the thoracic spine.

KEY WORDS • image guidance • ligamentum flavum • ossification • thoracic spine

WHEN thoracic myelopathy due to an OLF occurs, conservative treatment is not effective and surgery is often indicated. Because OLF is found in the posterior part of the thoracic canal, a posterior laminectomy has been performed.^{1,2,5} Although controversy exists, it has been reported that laminectomy occasionally causes early- or late-onset complications due to scar formation in the epidural space and increased kyphotic deformity, especially at the thoracolumbar junction.² To prevent these complications, some surgeons have adopted laminotomy with medial facetectomy to resect the OLF while preserving the spinous processes with the supra- and interspinous ligaments, the cranial part of each lamina, and the lateral facets.³ This procedure is theoretically superior to conventional wide laminectomy in that the posterior structures of the spine are preserved. An OLF causing myelopathy, however, is usually large and its shape is irregular. Moreover, the spinal cord becomes debilitated by the severe long-term compression. Therefore, resection of the OLF via either conventional laminectomy or laminotomy remains demanding because of the risk of intraoperative iatrogenic spinal cord injury. To increase safety and make possible the precise resection of the OLF, we have used an image guidance system. In this article, this technique and its preliminary results are reported.

Abbreviations used in this paper: CT = computerized tomography; JOA = Japanese Orthopaedic Association; OLF = ossified ligamentum flavum; 3D = three-dimensional.

Clinical Material and Methods

Patient Population

Between October 1999 and June 2002, we performed laminotomy with medial facetectomy and imaging-guided resection of the OLF of the thoracic spine at the Tokyo University Hospital in 10 patients. There were two women and eight men, and their mean age at surgery was 56 years (range 44-67 years). Gait disturbance caused by thoracic myelopathy was present in all patients. Demographic and surgery-related data are summarized in Table 1. The surgery was performed by one surgeon. The follow-up duration ranged from 6 to 37 months (mean 20 months). In the course of the same surgery, cervical double-door laminoplasty was performed in two patients with concomitant cervical spondylotic myelopathy,⁴ anterior decompression and fusion of the thoracic spine was performed in one with ossification of the posterior longitudinal ligament, and lumbar laminotomy was performed in a fourth patient with lumbar spinal canal stenosis.

Surgical Procedure

We used a frameless stereotactic image guidance system (StealthStation; Medtronic Sofamor Danek, Memphis, TN). Preoperative axial CT scans (1.25-mm slices) of the thoracic spine were obtained in all patients. The data were transmitted to the computer workstation and were reconstructed into two-dimensional and 3D images of the vertebrae and OLF. The OLF can be visualized in color by using the system's painting tool. The image guidance system was used as the first step for preoperative surgical planning, in particular to

determine the margins of the area to be resected while preserving the lateral parts of the facet joints (Fig. 1).

With the patient placed prone, a midline incision was made. The spine was exposed, taking care to preserve the supra- and interspinous ligaments. After the laminae and transverse processes were exposed, the surgical reference frame was attached to each spinous process of the OLF-affected vertebra. Following registration, we thinned the laminae and medial parts of the facet joints by using an air drill, according to the image guidance system that showed the location of the OLF. We were able to see through the OLF hidden by the laminae on the monitor screen and to

identify its location in the surgical field. The thinned and floating OLF was gently separated from the dura and removed using a rongeur. The remaining nonossified yellow ligament was removed easily by using a curette or a rongeur. As the final step, we used the image guidance system and ultrasonography to confirm that decompression was accurately achieved.

Clinical Evaluation

The severity of thoracic myelopathy was evaluated by determining lower-extremity motor scores with the JOA

FIG. 1. Images obtained using the real-time guidance system. The tip of the instrument (blue) shows the lateral margins of the area to be resected. The OLF (yellow) can be seen through the laminae on the 3D CT scan.

TABLE 2
Details of the JOA classification system
for lower-extremity motor function

Function	Score

needs cane or aid only on stairs	2
can walk w/out cane or aid, but slowly	3
no disability	4

scale for cervical myelopathy (Table 2). The surgery-related results were graded as excellent when there was an increase/recovery of two points in the lower-extremity motor JOA score (full score is 4); good with an increase/recovery of one point; unchanged with no alteration in score; and poor when motor function worsened after surgery.

Neuroimaging Evaluation

Postoperative CT scans and magnetic resonance images were obtained to confirm that a precise resection of the OLF and cord decompression were achieved. By comparing pre- and postoperative 1.25-mm axial CT scans, we investigated whether the lateral parts of facet joints at the surgically treated vertebrae were preserved (Fig. 2A). We also assessed the progression of postoperative kyphotic deformity and/or anterior vertebral slippage, on preoperative and follow-up lateral thoracic radiographs (Fig. 2B and C). Two cases were excluded from radiological evaluation; in these cases clear radiographs could not be obtained because the treated sites were at the cervicothoracic junction.

Results

We could visualize the location of the OLF before surgery in virtual reality. In all cases, the OLF was situated between the caudal edge of the pedicle and the caudal edge of each lamina. Thus, minimal resection of the cra-

nial part of each lamina allowed removal of the OLF. The mean fiducial error at the intraoperative registration ranged from 0.4 to 0.9 mm (mean 0.6 mm).

Surgery-related results were good in seven patients and excellent in three. No neurological deterioration occurred. Postoperative CT scans revealed the absence of any residual OLF, and greater than 30% of the lateral parts (mean 51%, range 30–78%) of the facet joints were well preserved in all cases (Fig. 3). Additionally, MR imaging demonstrated that the spinal cord was adequately decompressed. During the follow-up period, because the change in thoracic kyphosis (Fig. 2B) was within 2° in all cases, we judged that no significant kyphotic deformity progression had occurred at the treated level. Anterior vertebral slippage (Fig. 2C) did not develop in any case.

Discussion

Ossification of the ligamentum flavum of the thoracic spine is not a rare disease in the Japanese population, and laminectomy has frequently been used in the treatment of this disease.^{1,2,5} Laminotomy has been widely performed in patients with lumbar spinal stenosis, but in the thoracic spine it has not been a common procedure.³ As a minimally invasive procedure, laminotomy is superior to conventional wide laminectomy if intraoperative safety is maintained. The resection of the posterior elements including the interspinous ligaments and the facet joints compromises spinal stability. Okada, et al.,² reported several patients with an OLF in whom postlaminectomy deterioration secondary to increased kyphotic deformity of the thoracic spine was demonstrated. On the other hand, the accurate removal of an OLF is not technically easy via either laminectomy or laminotomy. Although a wide laminectomy makes the decompressive maneuver easier, it increases the risk of destroying the entire facet joint. Technical improvement of the decompressive procedure for an OLF is essential.

The computer-assisted image guidance system has been developed to improve the surgeon's ability to identify anatomical landmarks for complex procedures, such as

FIG. 2. Radiographic measurements for the thoracic spine. A: The residual ratio of the lateral part of a facet joint on CT scans was determined as the following: $b/a \times 100\%$. B: Degrees of thoracic kyphosis. The angle (α) formed by the two lines drawn along the posterior margin of the adjacent two vertebral bodies was measured. C: Anterior vertebral slippage.

Image-guided surgery for ossification of the ligamentum flavum

FIG. 3. Case 10. Computerized tomography scans obtained in a man who underwent resection of an OLF at T9–11 when he was 44 years of age. *Left:* Preoperative axial CT scan (obtained at T-9) demonstrating the OLF. *Center:* Postoperative CT scan (at almost the same level) demonstrating that the OLF was removed while preserving the lateral parts of the facet joints. *Right:* Postoperative 3D CT scan revealing that laminotomy with medial facetectomy was achieved precisely.

pedicle screw insertion and C1–2 transarticular screw fixation. The operative field and preoperative images are combined by registration, or integration, of the preoperative imaging modalities with the surgical world. To increase the safety and accuracy of posterior decompressive surgery in patients with OLF, we used the computer-assisted imaging guidance system.

The follow-up period is not yet long enough in some patients to determine if postoperative deformity will occur. Nevertheless, evaluation of our results shows that our technique allows accurate decompression while preserving much of the facet joints, and the short-term results were encouraging.

Conclusions

An OLF of the thoracic spine can be effectively resected using an image guidance system.

KEY WORDS • meningioma • schwannoma • neurofibromatosis Type 2 • cervical spine

The coexistence of spinal schwannoma and meningioma is very rare.^{1,2,4} We present a case of a 54-year-old woman in whom this condition was diagnosed.

The patient noticed a slowly growing mass on the right side of her neck and experienced left upper-extremity numbness and mild gait disturbance. Magnetic resonance (MR) imaging demonstrated a dumbbell-type tumor involving the right-sided C-5 nerve root and three intradural extramedullary tumors at C-4, C-5, and T-1 levels (Fig. 1, tumors A–D). Tumors A and D exhibited the following characteristics of schwannoma: MR imaging signal intensities and Gd–diethylenetriamine pentaacetic acid (DTPA) enhancement patterns, whereas tumors B and C exhibited dural tail sign,⁵ characteristic of meningioma (Fig. 1). In her family history, her mother harbors asymptomatic multiple cauda equina schwannomas.

We resected all four spinal tumors under an operative microscope. The intraoperative pathological diagnosis confirmed that tumors A and D were schwannomas and tumors B and C were meningiomas. We therefore performed bipolar electrocoagulation to the dura adjacent to tumors B and C.

Postoperatively, the lower-extremity sensory disturbance and gait disturbance improved. Right-sided deltoid and biceps brachii weakness occurred, and there was partial recovery by 24 months.

Although multiple and familial spinal tumors have been thought to be associated with neurofibromatosis Type 2 (NF2), our case does not strictly meet National Institutes of Health criteria for NF2.³

Schwannoma and meningioma have different radiological characteristics and require different procedures; therefore, it is important to distinguish these tumors prior to surgery to determine an optimal surgical plan.

Image-guided surgery for cervical disorders in rheumatoid arthritis

Received: December 1, 2001 / Accepted: April 17, 2002

Abstract This study demonstrated that frameless stereotaxy can be applied safely to cervical disorders caused by rheumatoid arthritis (RA). Sixteen patients with cervical instability including atlantoaxial instability due to RA underwent instrumentation surgery under an image-guidance system from February 2000 through May 2001. Neural and vascular injuries were evaluated, and postoperative computed tomography (CT) was used to determine the accuracy of screw placement. There were no neurovascular complications, and screw placement was highly accurate. Image-guidance systems are useful tools for preoperative planning and application of transarticular and pedicular screw placement in the cervical spine of patients with RA.

Key words Cervical spine · Frameless stereotaxy · Image guidance · Rheumatoid arthritis (RA)

Introduction

Cervical disorders caused by rheumatoid arthritis (RA) include atlantoaxial (C1/2) instability and subluxation in the mid- and low-cervical spine. These conditions sometimes cause myelopathy, severe pain, or both, either of which impairs the quality of life of RA patients.¹ In such cases surgery may be indicated. Posterior procedures using wiring or hook systems have been employed, but they sometimes result in loss of reduction or nonunion.^{2,3} C1/2 transarticular screws have been adopted by many surgeons to achieve C1/2 stabilization, and pedicular screws have also become an option to achieve occipitocervical and intercervical sta-

bilization.^{4,5} Both techniques provide greater biomechanical stability than conventional posterior fusion methods,^{6,7} but these procedures are technically demanding and pose the potential risk of neurovascular injuries.^{8–10}

Frameless stereotactic technology was first designed for intracranial surgery for guidance of unseen lesions. An image guidance system for spinal surgery was developed for installation of pedicle screws in the lumbar spine. The principle of this system is that the anatomy of the patient is related precisely to the image data, making it possible to achieve preoperative surgical planning and intraoperative monitoring of the three-dimensional positioning of the surgical field in real time. Using this system we can make a preoperative surgical plan of the screw trajectory; and the intraoperative screw position can be confirmed in the virtual field on the computer screen. To improve the accuracy of screw placement in the cervical spine of patients with RA, we have adopted an image-guidance system and herein report the usefulness and the limitations of this technique.

Materials and methods

From February 2000 through May 2001 a total of 16 patients with cervical disorders due to RA were treated surgically using the image-guidance system. There were 11 women and 5 men with a mean age at the time of surgery of 62 years (range 49–74 years). The cervical disorders were atlantoaxial instability in 15 and subaxial instability in 1. All the patients had a myelopathy, and two had severe neck pain. According to the Ranawat classification,¹ the neurologic deficits were class 2 in three, class 3A in eight, and class 3B in five. Twelve patients underwent C1/2 transarticular screw fixation (Magerl's procedure)⁴; three underwent occipitocervical fusion combined with C1/2 transarticular screws using the Olerud cervical system (Nord Opedic, Askim, Sweden); and one patient underwent posterior instrumentation with pedicular screws using the Olerud cervical system at the cervicothoracic junction. All patients had autogenous iliac bone grafts. They were allowed and en-

couraged to stand 1 week after surgery and wore a simple cervical collar 3–4 months after surgery.

We used a frameless stereotactic image-guidance system (Stealth Station; Sofamor Danek, Memphis, TN, USA) for correct screw fixation of the cervical spine (Fig. 1). Pre-operative computed tomography (CT) scans (1.25-mm axial slices) with contrast medium in the cervical spine of the

Fig. 1. Operative setup of the image-guidance system. The infrared camera is positioned at the cranial end of the patient (arrow). The probe with light-emitted diodes (arrowhead) is tracked by the infrared camera system, and the position of the probe is displayed on the computer monitor screen

patient were obtained (Light Speed QX/i; GE, Fairfield, CT, USA). The data were translated to the computer workstation of the system to reconstruct two- and three-dimensional images of the vertebrae and the vertebral artery, which was shown using contrast medium.

A surgical plan in which 4 mm diameter screws were set to pass the pedicles was devised before surgery on the computer monitor image (Fig. 2). For C1/2 transarticular fixation, C2 was the planned target because the vertebral artery is located close to the course of the screwing (Fig. 3) and the intraoperative spatial relation of C1 to C2 is different in the surgical field from that in the computer field. As reported in Magerl and Seemann's original article,⁴ the virtual entry point of a screw was created at the caudal edge of the C2/3 joint. The exit point from C2 was located in the dorsal half of the upper joint surface to avoid the vertebral artery. For pedicular screwing in the vertebrae below C2, a surgical plan of the screw trajectory was devised for each vertebra to which a screw was to be inserted. As Abumi et al. reported,⁵ the virtual entry point was slightly lateral to the center of the articular mass and close to the inferior margin of the inferior articular process of the cranially adjacent vertebra. The insertion angle in the sagittal and coronal planes and the length of screwing were determined in the virtual field on the computer screen.

A posterior approach was employed for all cases. For C1/2 transarticular fixation, C1–4 laminae were exposed. Two small stab wounds were made at the cervicothoracic junction to provide the optimal trajectory for screw insertion, if necessary. For occipitocervical fusion, the occipital

Fig. 2. Computer display shown at surgery. The position of the device and surgical plan are shown in four views. The wide white arrow indicates the position and direction of the device, and the narrow gray arrow indicates the planned screw trajectory

protuberance to the lowermost cervical fusion vertebra was exposed.

The surgical reference frame was attached intraoperatively to the spinous process of C2 for C1/2 transarticular fixation or each spinous process of the vertebra for pedicular screw insertion. Registration was performed by identifying four or five points on the vertebra in the surgical field and the corresponding points on that vertebra on the monitor. More precise matching was obtained by indicating 30 or more randomized points on the surface of the posterior elements of the vertebra with the probe (surface registration). If the considered complete accuracy calculated by this computer system was within 1mm, registration was concluded. The system then allowed the surgeon to proceed with preparation of the pilot hole. The positions of the entrance holes for screws were made by an air drill, and the holes were deepened by a pedicle probe according to the planned screw trajectory shown by the navigation probe with light-emitting diodes on the monitor screen. For pedicular screwing below C2, a 4.0-mm self-tapping screw of appropriate length was inserted into the hole under guid-

ance of the computer system. For transarticular fixation of C1/2, a Kirchner wire was inserted into the hole. An intraoperative X-ray image was used when this wire was inserted into the atlas, which was repositioned by manually pushing the C2 spinous process forward. The target point for this wire was the anterior arch of C1 seen on the fluoroscope screen; and the length of the screws was determined by measuring the inserted wire. Self-tapping cannulated titanium screws 4mm in diameter were then inserted under computer guidance with simultaneous fluoroscopy.

Transverse and sagittal sections were generated to evaluate screw positions with postoperative 1.25-mm slice CT scans. Screw positions were graded into three groups: grade 1, perfectly placed screws; grade 2, partial cortical perforations lower than 2mm; grade 3, all perforations larger than 2mm.¹¹

Results

The mean fiducial error at the intraoperative registration ranged from 0.3 to 0.8mm (average 0.5mm). A total of 38 screws, including 30 C1/2 transarticular screws and 8 pedicular screws, were inserted using frameless stereotaxy. There were no neurovascular injuries. All 38 screws were exactly inserted inside the pedicles without perforating the bone cortex of the pedicles and so were evaluated as grade 1 (Fig. 4). No instrumentation failure, loss of reduction, or nonunion had occurred at the final follow-up (average 9 months; range 6–20 months). The myelopathy had been alleviated in all patients.

Discussion

Transpedicular screw fixation including C1/2 transarticular screw fixation is biomechanically superior to other conventional procedures using wiring or clamping.^{4,7} Both C1/2 screw placement and pedicular screwing in the subaxial

Fig. 3. Spatial relation of the planned screw trajectory (white bars) in regard to the vertebral artery, which is located close to the course of screwing at the cranial end of C2 (arrowheads)

Fig. 4. Postoperative computed tomography (CT) scan of C1 and C2 in a 73-year-old man with transarticular fixation between C1 and C2. The transarticular screws correctly pass through the pedicle of C2

cervical spine depends on anatomic landmarks and intraoperative fluoroscopy. However, because anatomic landmarks are not always reliable, especially when the vertebral artery runs an abnormal course, screw placement has a potential risk of neuro-vascular injury. Clinical reports on C1/2 transarticular screw fixation have indicated that screw misplacement occurred in up to 15% of patients and injury to the vertebral artery in 2%–4%.^{6–9}

It is difficult to evaluate the abnormal position of the vertebral artery by conventional two-dimensional images including CT scans, magnetic resonance imaging (MRI), and angiography. Moreover, the bony structure of the vertebrae of Japanese patients with RA is generally small and osteoporotic, and in such cases the risk of vertebral artery injury increases if fluoroscopy alone is used. One option to reduce this risk is image-guided surgery. Surgical planning with the computer-guidance system allows better recognition of the complex three-dimensional anatomy of the cervical spine in RA patients. The optimal screw trajectory can be planned on the computer screen prior to surgery; and by matching the surgical field with the virtual field on the screen, surgeons can insert screws according to the preoperatively planned optimal trajectory.

The usefulness of computer assistance for pedicle screw installation in the thoracic and lumbosacral areas has been reported.¹¹ The accuracy of a computer-assisted image-guidance system for correct pedicle screw fixation of the cervical spine has been confirmed in laboratory tests,¹² but its clinical results in RA patients have not yet been clarified. The current study was not large, but the results of surgery under the image-guidance system were encouraging. Use of this system in cervical instrumentation surgery for RA patients can aid in reducing the risk of screw misplacement.

At the time of preoperative CT examination, complete reduction of C1/2 subluxation by positioning is difficult. Hence the intraoperative spatial relation of C1 to C2 and possibly the course of the vertebral artery outside the C2 vertebra are different in the surgical field from that seen in the computer field. Therefore, the area of navigation during C1/2 transarticular fixation is limited to C2. Fluoroscopy is essential to confirm the position of C1. It is hoped that development of more sophisticated software will permit navigation of all mobile segments. Another limitation of the

image-guidance system is that achieving perfect installation of screws according to the preoperatively planned optimal trajectory requires complete handling of hardware including a pedicle probe and motor system. Robotic surgery for screw installation may be an option in the near future.

Based on the fact that the *klotho*-deficient mouse exhibits multiple aging phenotypes, including osteopenia and subchondral sclerosis of joints, we explored the possibility of whether human *klotho* gene polymorphism is associated with two major age-related skeletal disorders: osteoporosis and spondylosis. Analysis of the CA repeat sequence downstream of the final exon of the *klotho* gene identified ten types of alleles in Japanese postmenopausal women ($n = 377$). We investigated the association of this microsatellite polymorphism with bone density and spondylosis score of the lumbar spine. None of the genotypes was associated with bone density in the overall population ($n = 377$; 754 alleles) nor in the subpopulation at not more than 10 years after menopause (≤ 10 years, $n = 131$; 262 alleles). However, the type 5 allele was significantly associated with low bone density in aged subpopulations at 10–20 years after menopause ($n = 144$; 288 alleles, $p = 0.035$) and > 20 years after menopause ($n = 102$; 204 alleles, $p = 0.024$). The type 7 allele was associated with high bone density in women more than 20 years after menopause ($p = 0.042$). The association study with spondylosis of postmenopausal women ($n = 221$) revealed that another distinct allele, type 8, was significantly associated with low spondylosis score at L-4/5 ($p = 0.019$) and L-5/S-1 ($p = 0.048$) levels in the subpopulation equal to or younger than the average age (≤ 63 years old, $n = 119$; 238 alleles), but not in the older subpopulation. These findings indicate that the *klotho* gene may be a candidate for the genetic regulation of common age-related diseases like osteoporosis and spondylosis, and we provide the first evidence suggesting that this gene may be involved in the etiology of human diseases. Introduction

Aging is one of the most important factors contributing to the incidence and progression of various diseases. Osteoporosis and osteoarthritis, including spinal spondylosis, are common skeletal disorders associated with age-related changes in bone and cartilage. Osteoporosis is a systemic disorder of decreased skeletal mass as measured by bone density, and by disturbed skeletal architecture and function that results in an increased risk for bone fractures with consecutively increased morbidity and mortality. Because twin and sibling studies have revealed that the proportion of variance of bone density accounted for by genetic factors is around 50%–90%,^{7,9,25,30,32,39} it is clear that variation in bone density between individuals is determined largely by genetic factors. Linkage studies on the whole genome screening have defined multiple loci that regulate bone density, but the genes responsible for these effects remain to be defined.^{5,6,24,29} Population-based studies and case-control studies have similarly identified polymorphisms in several candidate genes, such as vitamin D receptor, estrogen receptor, and collagen I $\alpha 1$ genes, that have been associated with bone density.^{12,17,23,28} However, this is controversial and genetic components of osteoporosis are not completely understood.^{11,13,36}

Osteoarthritis is also considered a collective result of heterogeneous etiopathologic factors affecting cartilage, the most prominent of which are disorders in joint biochemistry or biomechanics. Family studies have suggested not only osteoarthritis of the knee and hand,^{8,16,33} but also of the spine—spondylosis^{2,31}—has a strong genetic component with an increased prevalence in first-degree relatives of affected individuals. A population-based study of twins demonstrated a clear genetic effect for radiographic osteoarthritis of the knee and hand in women, with 39%–65% of the variance being attributable to genetic factors.³³ Several recent investigations have suggested mutations or polymorphisms in several genes associated with either the development or severity of osteoarthritis; such genes include those encoding type II procollagen, type XI collagen, the vitamin D receptor and transforming growth factor (TGF)- β .^{1,20,22,34,37,38} In addition, the autosomal-dominant disorders, pseudoachondroplasia and multiple epiphyseal dysplasia, have

been linked to the gene for cartilage oligomeric matrix protein (COMP). Several mutations in this protein have also been implicated in dysplasias associated with early-onset osteoarthritis.^{3,15} However, the genetic susceptibility to osteoarthritis, including spondylosis, is not fully understood.

We recently identified a gene termed *klotho* that may be involved in the suppression of aging. The *klotho*-deficient mouse has exhibited a syndrome analogous to human aging.²⁶ This syndrome includes such maladies as a shortened lifespan, infertility, arteriosclerosis, osteopenia, subchondral sclerosis of joints, skin atrophy, premature thymic involution, ectopic calcification, lipodystrophy, and pulmonary emphysema. The *klotho* gene encodes a novel single-pass membrane protein that has a physiological function that remains to be determined.²⁶ Osteopenia observed in *klotho*-deficient mice is accompanied by low turnover during bone metabolism, which recapitulates the pathophysiology of senile osteoporosis in humans.¹⁸ In addition, subchondral sclerosis of joints in *klotho*-deficient mice resembles that observed in osteoarthritis in humans.^{18,26} These observations have led to the hypothesis that the *klotho* gene may be involved in the pathophysiology of osteoporosis and osteoarthritis in humans. The human homolog of the *klotho* gene is composed of five exons ranging over 50 kb on chromosome 13q12.²⁷ Here we identified a highly polymorphic dinucleotide repeat (cytosine-adenine; CA repeat) at ~10 kb downstream of the fifth exon. To examine the possible contribution of the *klotho* gene to the development of age-related diseases in humans, we investigated the association of the polymorphic microsatellite marker with bone density and spondylotic changes of the lumbar spine in postmenopausal Japanese women. This is the first report on the involvement of the *klotho* gene in the etiology of human diseases.

Materials and Methods

Patients

Genotype analysis by the polymorphic CA repeat marker was carried out using genomic DNA extracted from peripheral blood samples obtained from 377 healthy postmenopausal Japanese women living in Nagano prefecture. The clinical characteristics of these women recruited for the study were as follows (mean \pm SD): age, 65.6 \pm 9.3 (range 41–91) years; height, 150.1 \pm 3.7 cm; weight, 52.1 \pm 4.3 kg; body mass index (BMI), 23.7 \pm 3.2 kg/m²; years since menopause, 14.7 \pm 7.2 years. Exclusion criteria included endocrinological disorders (e.g., hyperthyroidism, hyperparathyroidism, diabetes mellitus), liver or renal diseases, use of medications known to affect bone metabolism (e.g., estrogen, bisphosphonates, vitamin D, calcium supplement, corticosteroids, anticonvulsants, heparin), and unusual gynecological history. All patients were unrelated volunteers who gave informed consent before the study. Patients were divided into three subpopulations according to the period after menopause: not more than 10 years after menopause (≤ 10 years, $n = 131$; 262 alleles); more than >10 years but not more than 20 years (10–20 years, $n = 144$; 288 alleles); and more than 20 years (>20 years, $n = 102$; 204 alleles).

For the association study with the spondylotic change in the lumbar spine, 221 women (45–91 years, 63.5 \pm 8.2 years old) out of the aforementioned 377, whose lateral X-rays of the lumbar spine for spondylosis scoring were available, were analyzed. These patients were also divided into two subpopulations: those equal to or younger than the average age (≤ 63 years old, $n = 119$; 238 alleles) and those older than the average age (>63 years old, $n = 102$; 204 alleles).

Measurements of Phenotypes

Bone mineral density (BMD; milligrams per square centimeter) of the second through the fourth lumbar spine (L2–4) was measured by dual-energy X-ray absorptiometry (DPX-L, Lunar, Madison, WI). This parameter was expressed as a Z score, which is a deviation from the weight-adjusted average BMD of each age based on data of 20,000 Japanese women provided with the Lunar DPX-L. The severity of spondylotic change at L-4/5 and L-5/first sacrum (S-1) was graded on a five point scale (0–4) according to Kellgren–Lawrence scoring²¹ on a lateral radiograph of the lumbar spine under standardized conditions.

Determination of Microsatellite Polymorphism

Polymerase chain reaction (PCR) was performed using oligonucleotide primers designed to amplify the polymorphic CA repeat downstream of the final exon of the human *klotho*. The reaction was carried out in a final volume of 25 μ L containing 100 ng of genomic DNA obtained from peripheral white blood cells, 10 pmol of each fluorescence primer (primer 1: 5'-CAGGGTATGATCATACGCAGACC-3'; primer 2: 5'-AGGCTGCTGCA-GAATCTGC-3'), 200 mmol/L dinitrophenolphosphate [dNTP], 10 mmol/L Tris-HCl [pH 8.3], 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 0.001% gelatin, and 0.1 U Taq-DNA polymerase (Applied Biosystems, Foster City, CA), and 30 cycles (each for 30 sec at 94°C, 30 sec at 61°C, and 30 sec at 72°C) were performed (PE-9600, Applied Biosystems). The genotype for the *klotho* microsatellite was determined with a fluorescence-based automated DNA sequencer (Prism 310, Applied Biosystems). Sizes of the PCR products were determined by comparison with an external size marker (50–500 bp, Applied Biosystems) and analyzed with FRAGMENT MANAGER software (Applied Biosystems).

Statistical Analyses

The Z score, Kellgren–Lawrence score, body weight, and height were compared by analysis of variance (ANOVA) (STATVIEW J 4.5). Comparisons of the Z score of L2–4 BMD and the Kellgren–Lawrence score between an allele type and others were performed using an unpaired two-tailed Student's *t*-test (STATVIEW J 4.5). The chi-square test was used to assess Hardy–Weinberg equilibrium. $p < 0.05$ was considered statistically significant.

Results

Association of *Klotho* Gene Polymorphism With Bone Density of Postmenopausal Women

The allele type of the *klotho* gene was determined in each individual by PCR to amplify the genomic DNA fragment including the CA repeats downstream of the fifth exon, which identified ten different alleles in the 377 postmenopausal women. We named each polymorphism, type 1 through type 10, according to the number of CA repeats, as shown in Table 1. The distribution of allelic frequency was not different among the overall population ($n = 377$; 754 alleles), the subpopulation ≤ 10 years after menopause ($n = 131$; 262 alleles), that 10–20 years after menopause ($n = 144$; 288 alleles), and that >20 years after menopause ($n = 102$; 204 alleles) (Table 1). Deviation from Hardy–Weinberg equilibrium was not significant in any of the subpopulations (all $p > 0.05$). Neither mean age or years after menopause differed among allele types in any population, nor did
