
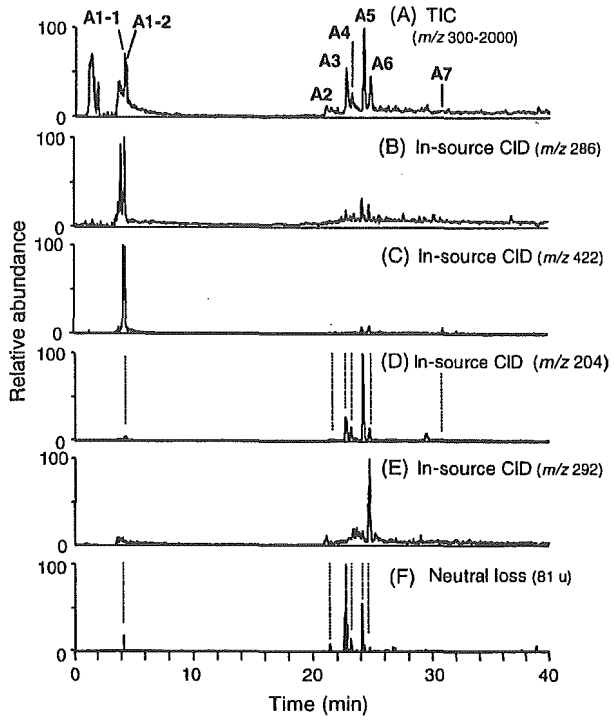

Fig. 6. Total ion chromatogram (TIC) of Asp-N digested protein at 20–25 kDa (*m/z* 300–2000) (A), mass chromatograms from TIC with ion-source CID of *m/z* 286 (B), 422 (C), 204 (D), and 292 (E), and neutral loss chromatogram of 81 u by data-dependent CID-MS/MS (F).

ion spectra. Glycopeptides in peak T2 were characterized as Ala73-Lys78 glycosylated at Asn74 with *N*-glycans consisting of $dHex_{0-2}Hex_{3-6}HexNAc_{2-5}$. These *N*-glycans can be identified as high-mannose-type oligosaccharide (M5), and complex-type and hybrid-type oligosaccharides containing Fuc attached to inner trimannosyl core GlcNAc. Their structural assignments are summarized in Table 1. Glycopeptides in peak T3 can be identified as a mixture of peptide His21-His31 and His21-Glu32 glycosylated at Asn23, and Ser96-Asp106 glycosylated at Asn98. Asn23 was attached by high-mannose-type oligosaccharides, M5, 6, and 7, and Asn98 was occupied by *N*-glycan consisting of $dHex_1Hex_4HexNAc_4$ with a Lewis a/x structure as a partial structure. Glycopeptides in peak T5 were characterized as peptide His21-Phe33 glycosylated at Asn23 with high-mannose-type oligosaccharide, M6. Glycopeptides in peak T7 were assigned to be Val69-Lys78 glycosylated at Asn74 with *N*-glycans composed of $dHex_{1-2}Hex_{4-6}HexNAc_{3-6}NeuAc$.

3.4. Analysis of the GPI moiety of rat Thy-1

Since trypsin digestion provided Cys-GPI, which could not be retained on the C_{18} column, Asp-N digestion was also performed to obtain more hydrophobic peptides attached by GPI (GPI-peptides). Fig. 6(A) shows the peptide/glycopeptide map obtained by LC/ITMS of Asp-N digested Thy-1. We localize the GPI-peptides using marker ions, EtN-PO_4-Man$^+$ at *m/z* 286 and GlcN-inositol-PO_4^+ at *m/z* 422, originating from the core structure of the GPI moiety by in-source CID (EtN, ethanolamine; GlcN, glucosamine). Mass chromatograms of *m/z* 286 and 422 suggest the locations of the GPI-peptides to be around 4.2 (peak A1-1) and 4.4 min (peak A1-2) (Fig. 6(B and C)). Using product ions originated from GPI moiety, such as GlcN-inositol-PO_4^+ and PO_4-Man-GlcN$^+$ (*m/z* 422 and 404), as marker ions, four product ion spectra of GPI-peptides were sorted out from all product ion spectra around peaks A1-1 and 1-2. Their precursor ions were doubly charged ions at *m/z* 1132 and 1213 (peak A1-1), 1051 and 1151 (peak A1-2). Based on these product ion spectra, we characterized GPI-peptides as the peptide Asp106-Cys111 with a GPI core structure plus Hex_{0-2}, $HexNAc_{1-2}$ and PO_4-EtN.

Fig. 7(A) shows the product ion spectrum of the doubly charged GPI-peptide ion at *m/z* 1051 in peak A1-2. In addition to product ions at *m/z* 422, those originating from the GPI moiety were detected at *m/z* 404 (PO_4-Man-GlcN$^+$), 447 (EtN-PO_4-Man-GlcN$^+$), 650 (EtN-PO_4-(HexNAc-)Man-GlcN$^+$), 787 (peptide-EtN$^+$), 868 (peptide-EtN-PO_4^+), 1191 (peptide-EtN-PO_4-Man-Man$^+$), 1477 (peptide-EtN-PO_4-Man-Man-(EtN-PO_4-)Man$^+$), 1638 (peptide-EtN-PO_4-Man-Man-(EtN-PO_4-)Man-GlcN$^+$), and 1898 (peptide-EtN-PO_4-Man-Man-(EtN-PO_4-)Man-GlcN-inositol-PO_4^+). From these fragments, it can be deduced that this peptide is Asp106-Cys111 carrying the GPI, as indicated in the inset in Fig. 7(A).

The other GPI-peptide in peak A1-1 was characterized as having side chains; -Hex attached to M1, -PO_4-EtN and -HexNAc attached to M3, based on the product ion spectrum of the doubly charged precursor ion at *m/z* 1132 (data not shown). These two GPI structures are identical to those that have been previously reported [24].

Product ion spectra of doubly charged ion at *m/z* 1151 and 1213 suggested that they contained GPI which bear one HexNAc or two Hex in addition to GPI in Fig. 7(A) respectively. Fig. 7(B) shows the product ion spectra of the doubly charged precursor ions at *m/z* 1151 in peak A1-2. In addition to *m/z* 422, we detected product ions at *m/z* 366 (HexNAc-Man$^+$), 447 (EtN-PO_4-Man-GlcN$^+$), 650 (EtN-PO_4-(HexNAc-)Man-GlcN$^+$), 1229 (peptide-EtN-PO_4-(HexNAc-)Man$^+$), 1391 (peptide-EtN-PO_4-(HexNAc-)Man-Man$^+$), 1676 (peptide-EtN-PO_4-(HexNAc-)Man-Man-(EtN-PO_4-)Man$^+$), 1838 (peptide-EtN-PO_4-(HexNAc-)Man-Man-(EtN-PO_4-)Man-GlcN$^+$), and 1880 (peptide-EtN-PO_4-(HexNAc-)Man-Man-(EtN-PO_4-)(HexNAc-)Man$^+$). These fragment ions suggest the attachment of -HexNAc to Man1, and -PO_4-EtN and -HexNAc to Man3 as indicated in the inset of Fig. 7(B). Similarly, product ion spectra of the doubly charged precursor ion at *m/z* 1213 indicate the attachment of 2Hex and HexNAc to Man1 and Man3-PO_4-EtN (data not shown). To our knowledge, this is the first report of these two GPI structures in Thy-1.

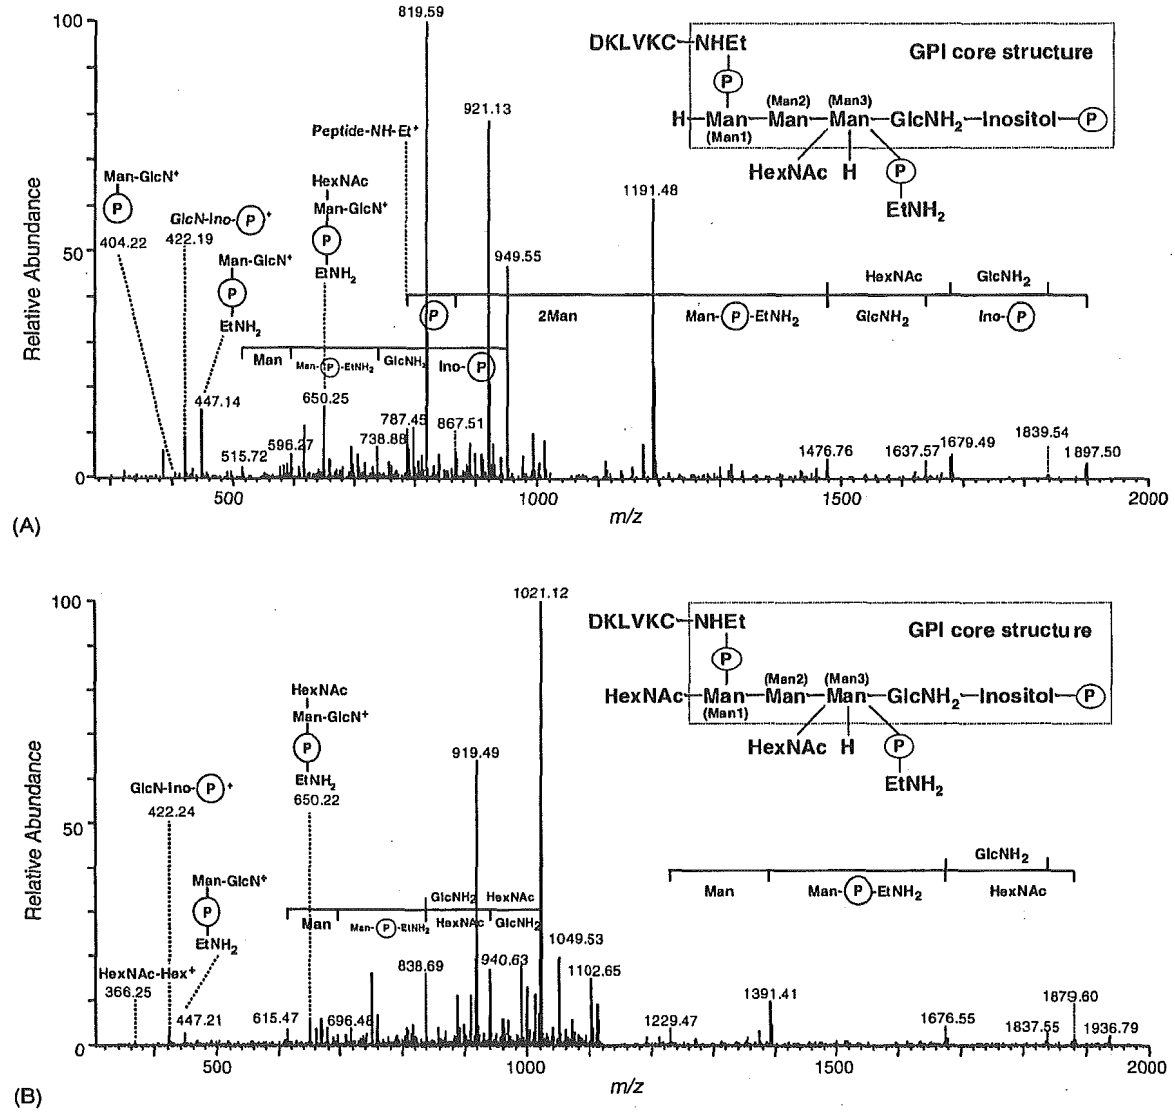

Fig. 7. Product ion spectra of the doubly charged GPI-peptide at *m/z* 1051 (A), and at *m/z* 1151 (B) in peak A1-2. The inset is the deduced structure of the GPI-peptide, and the core structure of GPI is the inside dashed line. Man, mannose; HexNAc, *N*-acetylhexosamine; $GlcNH_2$, glucosamine; $EtNH_2$-P, phosphorylethanolamine; Ino-P, inositol-phosphate.

3.5. Analysis of Asp-N digested Thy-1

Glycopeptides obtained by Asp-N digestion were also localized by in-source CID using marker ions at *m/z* 204 and 292 (Fig. 6(D and E)), and neutral loss of 81 u by data-dependent CID-MS/MS (Fig. 6(F)). Product ion spectra of glycopeptides were sorted by using B series ions as marker ions from those acquired around localized elution positions. Consequently, peaks A2-7 were identified as those of glycopeptides (Fig. 6(A)). The oligosaccharide structures in the glycopeptides were then characterized based on their product ion spectra (Table 1). In addition to the high-mannose-type oligosaccharides, M5, 6, and 7 deduced by LC/MS^n of tryptic digests, the oligosaccharide at Asn23 was characterized as $dHex_{0-1}Hex_{3,5,6}HexNAc_{3-5}NeuAc_{0,1}$, complex-type and hybrid-type oligosaccharides containing Lewis a/x or bisecting GlcNAc as a partial structure. Asn74 is attached by *N*-glycans with $dHex_{0-2}Hex_{3-6}HexNAc_{2,4,5}NeuAc_{0,1}$. They were high-mannose-type oligosaccharide, M5, complex-type oligosaccharides containing core Fuc and Lewis a/x as a partial structure, and hybrid-type oligosaccharides with core Fuc. Asn98 is occupied by high-mannose-type oligosaccharides, M5, and *N*-glycans with $dHex_{0-2}Hex_{3,5,6}HexNAc_{2-5}NeuAc_{0,1}$, hybrid-type oligosaccharides containing Lewis a/x or blood group H-determinant as a partial structure, which were found to be of greater diversity than those deduced by analysis of tryptic digests.

4. Discussion

In the present study, we have developed an efficient and convenient strategy for characterization, including protein identification and glycosylation analysis, of a small amount of unknown protein. We used gel electrophoresis, which is a powerful tool for separation of a small amount of protein from complex proteins mixture, especially from insoluble membrane fractions. For the complete glycosylation analysis, we examined the extraction of a whole glycoprotein from the gel, followed by trypsin digestion. Additionally, for the effective glycopeptide analysis, we studied mass spectrometric peptide/glycopeptide mapping by LC/MS^n with in-source CID and data-dependent MS^n. The glycopeptides were localized in the peptide/glycopeptide map by using oxonium ions as marker ions such as $HexNAc^+$ and $NeuAc^+$, which were generated by in-source CID, and neutral loss by data-dependent CID-MS/MS. For simultaneous identification of both peptides and glycopeptides, we conducted the database search analysis using search parameters containing a possible glycosylation at Asn with GlcNAc (203 Da). We successfully determined the sequences of peptides and some of the glycopeptides, which were localized by in-source CID and data-dependent CID-MS^n. The database search analysis using these search parameters was useful for identifying the glycopeptides resulting from predictable proteinase digestion. Glycopeptides caused by irregular digestion could be identified by assignment of peptide b and y series ions, which arose from further MS^n. The oligosaccharide structures of the identified glycopeptides were characterized on the basis of their product ion spectra. In this way, we were able to isolate rat brain Thy-1 and to elucidate *N*-glycosylation at Asn23, 74, and 98 as well as the structure of the GPIs at Cys111.

Post-translationally modified peptides could not be identified by the database search analysis. It has been particularly difficult to identify glycopeptides by database search analysis due to their complicated product ions resulting from the cleavage of glycosidic bonds. It has recently been reported that peptide + GlcNAc ion generated from a glycopeptide by CID-MS/MS yields b and y series ions by further MS^n, and that these ions can be utilized for identification of the peptide backbone and its glycosylation site [15,16,18]. Additionally, search analysis using the database including the possibility of glycosylation at Asn with all possible cleavage products of the known glycopeptides can be utilized for identification of glycopeptides in the peptide/glycopeptide map [19]. This ability would be helpful in the identification of glycoproteins whose glycosylation are already known. In the present study, we carried out a database search analysis using search parameters containing a possible glycosylation at Asn with only GlcNAc (203 Da), and successfully identified an unknown glycoprotein and *N*-glycosylated sites. This search analysis can be used for the identification of *O*-glycosylation, which has no consensus amino acid sequence, by using search parameters containing possible glycosylations at Ser/Thr with Hex, HexNAc, and dHex.

Precursor ion scans have been used for the localization the glycopeptides in peptide/glycopeptide mapping [10,11,13]. Although this method can be used for monitoring the peptides with predictable modification by setting mass of fragment ions prior to scanning, peptides with unpredictable modification cannot be detected. In contrast, in-source CID and CID-MS/MS are capable of localizing of the modified peptides after just one data acquisition using objective oxonium ions and neutral losses. In the present study, we were able to localize GPI-peptides in the peptide/glycopeptide map using $EtN\text{-}PO_4\text{-}Man^+$ and $GlcN\text{-}Inositol\text{-}PO_4^+$ generated by in-source CID [25] and to elucidate the GPI structures. We also could localize the glycopeptides with dHex, HexNAc, and NeuAc at the non-reducing ends as well as Hex using neutral loss by CID-MS/MS.

Site-specific glycosylation analysis of rat brain Thy-1 was performed after purification with monoclonal antibody affinity chromatography. Released oligosaccharides from fractionated trypsin-digested glycopeptides were analyzed by conventional analytical methods, including exoglycosidase digestion and methylation analysis [26]. In the present study, we separated PIPLC-treated GPI-anchored proteins of rat brain by SDS-PAGE, and conducted site-specific glycosylation analysis by LC/MS^n. Using a simpler step, we could elucidate the glycosylation at each glycosylation site with a greater variety of oligosaccharides than that reported previously and four GPI structures, including two novel attached structures.

Our strategy presented herein can relatively simply facilitate complete site-specific glycosylation analysis that used to require a series of complicated steps and is applicable to characterization of unknown proteins on 2-DE gel in proteomic study. Even in a mixture of multiple unknown glycoproteins, glycosylation of each glycoprotein can be determined based on the product ion spectra. Our method would be helpful for study of the alternation of glycosylation with growth, aging, and disease [27,28].

Ovomucoid · Allergen · Digestion · Simulated gastric fluid · Fragment, pepsin-digested · Human serum IgE

Abstract
Background: The allergenic potential of chicken egg white ovomucoid (OVM) is thought to depend on its stability to heat treatment and digestion. Pepsin-digested fragments have been speculated to continue to exert an allergenic potential. OVM was digested in simulated gastric fluid (SGF) to examine the reactivity of the resulting fragments to IgE in sera from allergic patients. ***Methods:*** OVM was digested in SGF and subjected to SDS-PAGE. The detected fragments were then subjected to N-terminal sequencing and liquid chromatography/mass spectrometry/mass spectrometry analysis to confirm the cleavage sites and partial amino acid sequences. The reactivity of the fragments to IgE antibodies in serum samples from patients allergic to egg white was then determined using Western blotting (n = 24). ***Results:*** The rate of OVM digestion depended on the pepsin/OVM ratio in the SGF. OVM was first cleaved near the end of the first domain, and the resulting fragments were then further digested into smaller fragments. In the Western blot analysis, 93% of the OVM-reactive sera also bound to the 23.5- to 28.5-kDa fragments, and 21% reacted with the smaller 7- and 4.5-kDa fragments. ***Conclusion:*** When the digestion of OVM in SGF was kinetically analyzed, 21% of the examined patients retained their IgE-binding capacity to the small 4.5-kDa fragment. Patients with a positive reaction to this small peptide fragment were thought to be unlikely to outgrow their egg white allergy. The combination of SGF-digestibility studies and human IgE-binding experiments seems to be useful for the elucidation and diagnosis of the allergenic potential of OVM.

Introduction

Chicken egg white is one of the strongest and most frequent causes of food allergies among young children [1–5]. Egg white contains several allergens, including ovalbumin, ovotransferrin, lysozyme and ovomucoid (Gal d 1, OVM). OVM accounts for about 11% of all egg white proteins [6] and has a molecular weight of 28 kDa, containing a carbohydrate content of 20–25% [7]. OVM is known to be stable to digestion and heat, and cooked eggs can cause allergic reactions in OVM-specific allergic patients [8–11]. One possible reason for this is that OVM contains linear epitopes that are only slightly affected by conformational changes induced by heat denaturation.

OVM consists of 186 amino acids divided into three domains of about 60 amino acids each; the third domain has been reported to be the most important domain with regard to allergenicity [12]. In a previous report, N-glycans in the third domain were suggested to be essential for allergenicity [13]; however, a recent report found that the deletion of the N-glycans did not affect the allergic reactivity.

We previously reported the digestibility of 10 kinds of food proteins in simulated gastric fluid (SGF) [8, 14]. OVM was digested relatively rapidly, but several fragments were detected by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) followed by Coomassie blue (CBB) staining. The reactivity of these fragments with IgE antibodies from the sera of patients with egg white allergy is very important to understanding the mechanism of OVM allergy.

A few previous reports have described the reactivity of IgE in sera from patients with egg white allergies with OVM-derived fragments. Kovacs-Nolan et al. [15] separated pepsin-digested fragments of OVM using high-performance liquid chromatography (HPLC) and examined the IgE-binding activities of each fragment using an enzyme-linked immunosorbent assay (ELISA). Besler et al. [16] investigated the reactivity of pepsin-digested fragments with patient IgE using Western blotting and showed that the fragments retain their binding capacity to human IgE in some serum samples from OVM-allergic patients. However, little attention has been paid to the digestive conditions, and the number of serum samples has been somewhat small in these studies. Urisu et al. [17] reported that the sera of subjects that tested positive or negative during an oral egg white challenge exhibited a significant difference in their reactivity with pepsin fragments.

In the present report, kinetic data for different generations of SGF-stable OVM fragments were obtained, and the reactivity of the fragments with serum IgE from patients with egg white allergies was investigated using Western blotting.

Materials and Methods

Pepsin (catalog number P6887) and chicken egg white OVM (T2011, Trypsin Inhibitor, Type III-O) were purchased from Sigma Chemical Co. (St. Louis, Mo., USA). The concentration of the OVM test solution was 5 mg/ml of water. The gels and reagents used for the SDS-PAGE analysis were purchased from Invitrogen (Carlsbad, Calif., USA).

Serum Specimens

Sera from 24 patients with egg white allergies and a healthy volunteer were used after obtaining informed consent from the patients and ethical approval by the Institutional Review Board of the National Institute of Health Sciences. Twenty-two of the patients had been diagnosed as having an egg white allergy at hospitals in Japan, based on their clinical histories and positive IgE responses to egg white proteins by radioallergosorbent test (RAST), while the remaining 2 allergen-specific sera were purchased from Plasma Lab International (Everett, Wash., USA); the commercial sera originated from adult Caucasians who had been diagnosed as having several food allergies, including egg white, based on their clinical history and skin tests. The commercial sera also showed positive IgE responses to egg white proteins when examined using RAST.

Preparation of SGF

Pepsin (3.8 mg; approximately 13,148 units of activity) was dissolved in 5 ml of gastric control solution (G-con; 2 mg/ml NaCl, pH adjusted to 2.0 with distilled HCl), and the activity of each newly prepared SGF solution was defined as the production of a $\Delta A280$ of 0.001/min at pH 2.0 and 37°C, measured as the production of trichloroacetic acid-soluble products using hemoglobin as a substrate. The original SGF was prepared at a pepsin/OVM concentration of 10 unit/μg, and this solution was diluted with G-con for the experiments performed at pepsin/OVM concentrations of 1 and 0.1 unit/μg. The SGF solutions were used within the same day.

Digestion in SGF

SGF (1,520 μl) was incubated at 37°C for 2 min before the addition of 80 μl of OVM solution (5 mg/ml). The digestion was started by the addition of OVM. At each scheduled time point (0.5, 2, 5, 10, 20, 30, and 60 min), 200 μl of the reaction mixture was transferred to a sampling tube containing 70 μl of 5 × Laemmli buffer (40% glycerol, 5% 2-mercaptoethanol, 10% SDS, 0.33 *M* Tris, 0.05% bromophenol blue, pH 6.8) and 70 μl of 200 m*M* Na_2CO_3. For the zero-point samples, the OVM solution (10 μl) was added to neutralized SGF (190 μl of SGF, 70 μl of 5 × Laemmli buffer, and 70 μl of 200 m*M* Na_2CO_3). All neutralized samples were then boiled at 100°C for 3 min and subjected to SDS-PAGE.

SDS-PAGE Analysis and Staining Procedure

Samples (15 μl/lane) were loaded onto a 10–20% polyacrylamide Tris/Tricine gel (Invitrogen, Carlsbad, Calif., USA) and separated electrophoretically. The gels were fixed for 5 min in 5% trichloroacetic acid, washed for 2 h with SDS Wash (45.5% methanol, 9% acetic acid), stained for 10 min with CBB solution (0.1% Coomassie Brilliant blue R, 15% methanol, 10% acetic acid), and destained with 25% methanol and 7.5% acetic acid. The stained gel images were then analyzed using Image Gauge V3.1 (Fuji Film, Tokyo, Japan), and the density of each band was quantified. Periodic acid-Schiff (PAS) staining [18] was used to detect the glycosylated fragments.

N-Terminal Sequence Analysis

OVM (1.5 mg) was digested in SGF containing 1 unit/ml pepsin, concentrated by centrifugation using Centriprep YM-3 (Millipore Corporation, Bedford, Mass., USA) and subjected to SDS-PAGE followed by electrical transblotting to a 0.2-μm polyvinylidene difluoride membrane (Bio-Rad, Richmond, Calif., USA) and CBB staining. The detected fragment bands were then cut out and sequenced using a Procise 494HT Protein Sequencing System (Applied Biosys-

tems, Foster City, Calif., USA) or an HP G1005A Protein Sequencing System (Hewlett-Packard, Palo Alto, Calif., USA); each fragment was analyzed for 5 cycles.

Carboxymethylation and Peptide Mapping Using Liquid Chromatography/Mass Spectrometry/Mass Spectrometry (LC/MS/MS)

The digested OVM sample was separated electrophoretically as described above, stained with CBB, and the stained bands were cut out. The gel pieces were homogenized in 20 m*M* Tris-HCl (pH 8.0) containing 0.1% SDS and the proteins were extracted. The extracts were concentrated and purified by acetone precipitation. The acetone precipitates were incubated with 2-mercaptethanol (92.5 m*M*) in 72 µl of 0.5 *M* Tris-HCl buffer (pH 8.6) containing 8 *M* guanidine hydrochloride and 5 m*M* EDTA at room temperature for 2 h. To this solution, 1.5 mg of monoiodoacetic acid was added, and the mixture was incubated at room temperature for 2 h in the dark. The reaction mixture was desalted using a MicroSpin G-25 column (Amersham Bioscience, Uppsala, Sweden) and lyophilized. Reduced and carboxymethylated proteins were digested with trypsin (50 ng/µl in 50 m*M* NH_4HCO_3).

Tandem electrospray mass spectra were recorded using a hybrid quadruple/time-of-flight spectrometer (Qstar Pulsar i; Applied Biosystems, Foster City, Calif., USA) interfaced to a CapLC (Magic 2002; Michrom BioResources, Auburn, Calif., USA). Samples were dissolved in water and injected into a C18 column (0.2 × 50 mm, 3 µm, Magic C18, Michrom BioResources). Peptides were eluted with a 5–36% acetonitrile gradient in 0.1% aqueous formic acid over 60 min at a flow rate of 1 µl/min after elution with 5% acetonitrile for 10 min. The capillary voltage was set to 2,600 V, and data-dependent MS/MS acquisitions were performed using precursors with charge states of 2 and 3 over a mass range of 400–2,000.

Western Blotting of Digested Fragments with Human Serum IgE

The digested OVM samples were applied to a 10–20% polyacrylamide Tris/Tricine 2D gel, followed by electrical transfer to a nitrocellulose membrane. The membrane was then blocked with 0.5% casein-PBS (pH 7.0) and cut into 4-mm strips. The strips were incubated with diluted human serum (1/4 to 1/5) in 0.2% casein-PBS (pH 7.0) at room temperature for 1 h and then at 4°C for 18 h. After washing with 0.05% Tween 20-PBS, the strips were incubated with rabbit anti-human IgE (Fc) antibodies (Nordic Immunological Laboratories, Tilburg, The Netherlands) at room temperature for 1 h, and then with horseradish peroxidase-conjugated donkey anti-rabbit Ig antibodies (Amersham Biosciences, Little Chalfont, UK) at room temperature for 1 h. Finally, the strips were reacted with Konica ImmunoStain HRP-1000 (Konica, Tokyo, Japan), according to the manufacturer's protocol.

Results

Kinetics of OVM Digestion by Pepsin

OVM was digested in SGF containing various concentrations of pepsin, and the fragments were separated by SDS-PAGE and stained with CBB (fig. 1). The molecular weight of OVM, based on its amino acid sequence, is about 20 kDa, but a broad band representing intact OVM appeared at about 34–49 kDa in the SDS-PAGE gel because of the presence of five N-linked sugar chains. The pepsin band was detected at 39 kDa, overlapping with the intact OVM band, and lysozyme (14 kDa) contamination was detected in the OVM sample that was used. Intact OVM rapidly disappeared within 0.5 min in SGF (pepsin/OVM = 10 unit/µg), and a fragment band was detected at 7 kDa. When the pepsin content in SGF was reduced to 1 and 0.1 unit/µg, the digestion rate markedly decreased. Intact OVM was still detected after 30 min when the pepsin/OVM ratio was 0.1 unit/µg. The fragment bands were clearer (fig. 2) when a concentrated SGF-digested OVM solution (pepsin/OVM = 1 unit/µg, digestion times 5 and 30 min) was used, followed by SDS-PAGE. As shown in figure 2, a strong 23.5- to 28.5-kDa band (FR 1) was detected at 5 min, while 10- (FR 2), 7- (FR 3) and 4.5- to 6-kDa (FR 4) bands were detected after 30 min. FR 1 and FR 2 were both positively stained by PAS, suggesting that the FR 1 and FR 2 fragments have high carbohydrate contents. The time courses for the amounts of intact OVM and the four fractions are plotted in figure 3, where the pepsin/OVM ratio is 1 unit/µg. FR 1 rapidly increased but slowly disappeared after 2 min. FR 2 and FR 3 also rapidly reached maximum values at 5 min and then slowly disappeared. On the other hand, FR 4 gradually increased throughout the entire period of the experiment.

Preheating (at 100°C for 5 or 30 min) of the OVM solution (5 mg/ml in water) did not influence the digestion pattern (fig. 1).

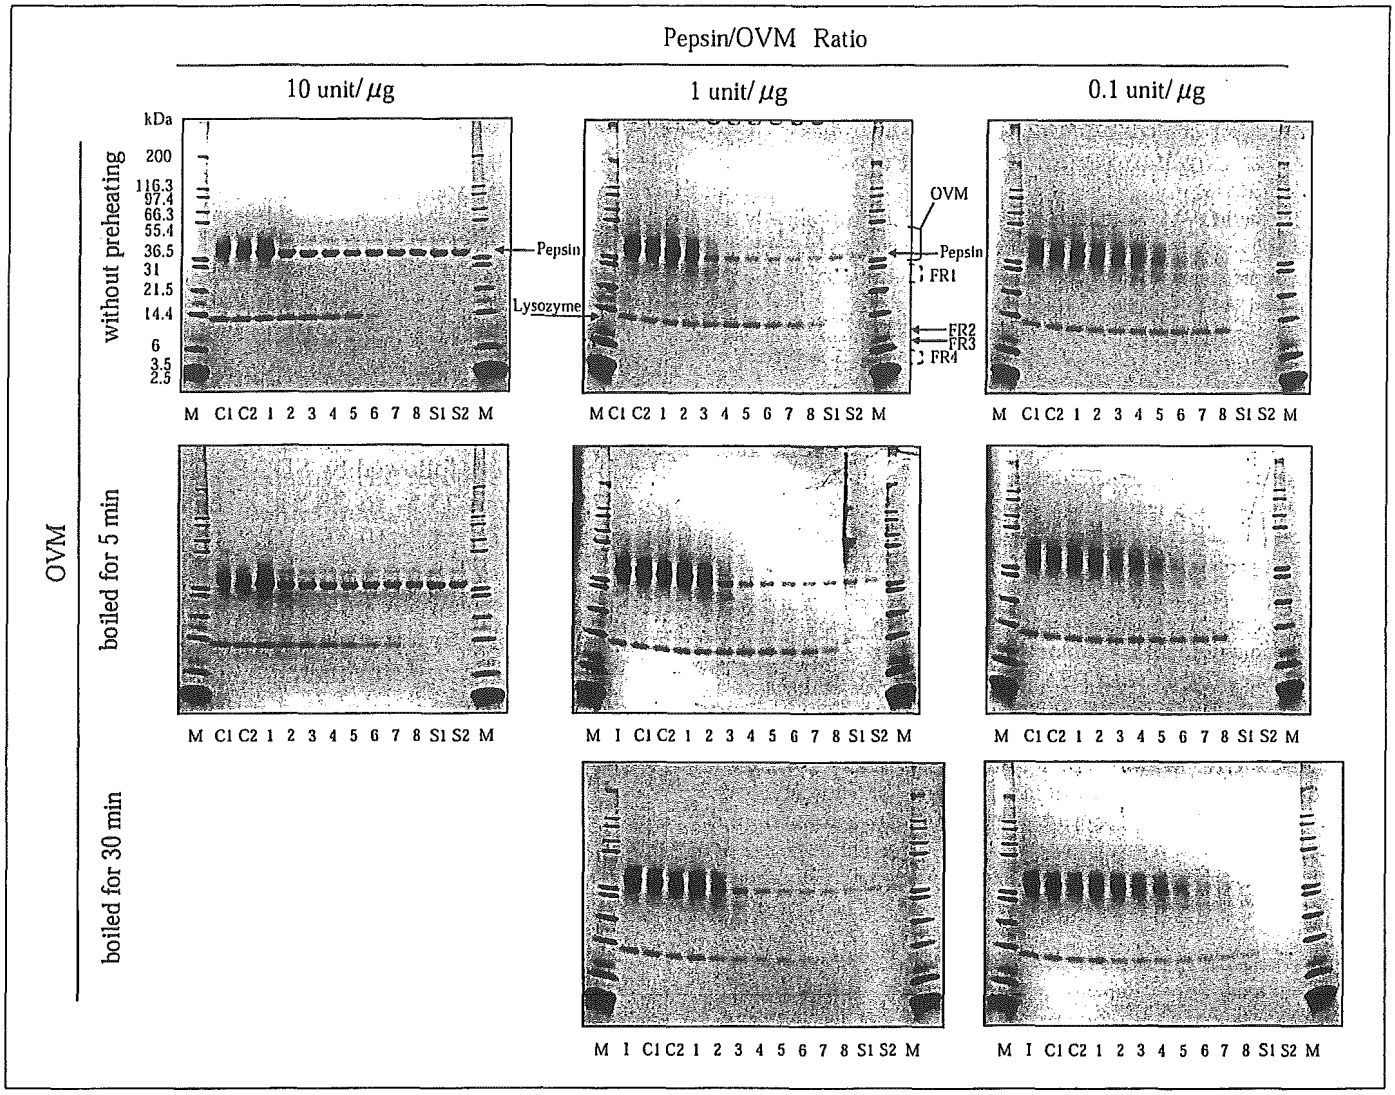

Fig. 1. Kinetic patterns of OVM digestion in SGF-containing pepsin. Digested samples were analyzed by SDS-PAGE followed by CBB staining. The digestion patterns of OVM without preheating (upper panels), preheated at 100°C for 5 min (middle panels), and preheated at 100°C for 30 min (lower panels) are shown. The ratio of pepsin to OVM was 10 unit/1 μg (left), 1 unit/1 μg (middle), and 0.1 unit/1 μg (right). Lane M = Molecular weight markers; lanes C1 and C2 = OVM without pepsin at 0 (C1) and 60 (C2) min; lanes 1–8 = SGF-digested OVM at 0, 0.5, 2, 5, 10, 20, 30 and 60 min, respectively; lanes S1 and S2 = SGF alone at 0 (S1) and 60 (S2) min; lanes I = OVM without preheating; FR 1 = fraction 1 containing a fragment at 23.5–28.5 kDa; FR 2 = fraction 2 containing a 10-kDa fragment; FR 3 = fraction 3 containing a 7-kDa fragment; FR 4 = fraction 4 containing 4.5- to 6-kDa fragments.

Sequence Analysis of OVM Fragments

The sequences of the five N-terminal residues in each fragment were analyzed, and the data are summarized in table 1. Figure 4 schematically depicts the identified fragments; the arrows in the upper panel indicate the sites of pepsin cleavage.

The internal sequences of the FR 1, FR 3, and FR 4 fragments were also identified by LC/MS/MS and are shown in table 2 and in the upper panel of figure 4.

Reactivity of the Fragments with Serum IgE from Patients with Egg White Allergy

Western blot analysis using patient sera as the source of the primary antibodies was performed to identify sera that reacted with intact OVM and the SGF fragments. Representative blotting data are shown in figure 5, and all the results are listed in table 3. Ninety-two percent of the serum samples from allergic patients reacted with OVM, and 93% of the OVM-positive sera reacted with FR 1

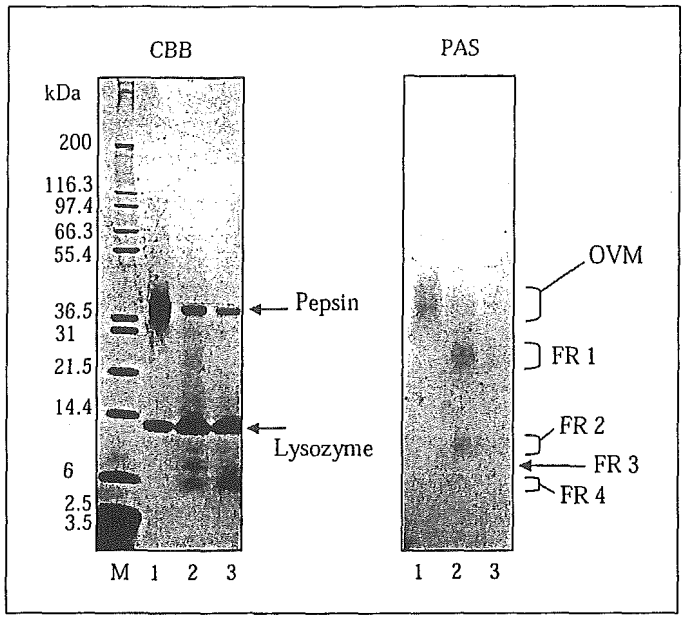

Fig. 2. CBB and PAS staining of OVM fragments following digestion in SGF (pepsin/OVM = 1 unit/μg) for 5 and 30 min. Lane M = Molecular weight markers; lane 1 = original OVM (2.5 μg/lane); lanes 2 and 3 = OVM digested for 5 and 30 min, respectively, and concentrated (12 μg, equivalent to the original OVM/lane). Samples were applied to two SDS-PAGE gels and electrophoresed. One plate (left panel) was stained with CBB reagent, and the other (right panel) was stained with PAS reagent.

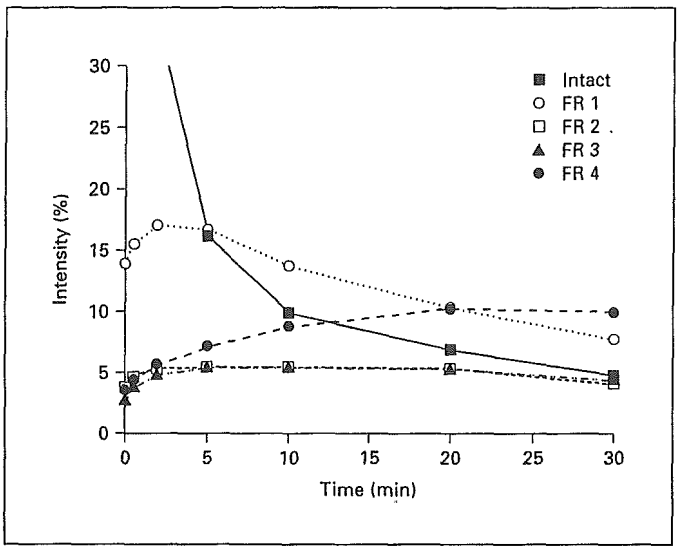

Fig. 3. Quantification of the SGF-digestion pattern of intact OVM and the digestion fragments at a pepsin/OVM ratio of 1 unit/μg. The intensity of each band was calculated using the ratio of the band's density to the total density of the originally detected band at $t = 0$. Values are the mean of duplicate analyses. Similar results were observed in another set of experiments.

after 5 min of digestion. Three of the serum samples also reacted with FR 2, FR 3, and FR 4 after 30 min of digestion.

The three samples that react with FR 2, FR 3, and FR 4 were obtained from patients who exhibited persistent allergies to egg white. One of these serum samples, No.4, was obtained from a 3-year-old girl who is presently 6 years old; her total IgE level has decreased slightly to 4,450 IU/ml, but the specific IgE level for egg white remains at more than 100 IU/ml, and the patient has not outgrown her hypersensitivity to eggs. Another patient, No. 13, was a 1-year-old boy; 7 years later, his total and egg white-specific IgE levels had been reduced to 947 and 6.85 IU/ml, respectively, but eating raw eggs still caused allergic symptoms. The third FR 4-positive patient, No. 19, was an 11-year-old boy whose total IgE level decreased to 3,940 IU/ml and whose egg white-specific IgE decreased to 13.5 IU/ml after a period of about 2 years; however, this patient has also not outgrown his allergies. These cases and our previously reported data [17] indicate that the induction of egg white tolerance may be difficult in patients whose serum IgE exhibits binding activity to digested small fragments of OVM.

Discussion

In the SGF-digestion system, preheating the OVM (100°C for 5 or 30 min) did not affect the OVM digestion pattern (fig. 1), consistent with the results of previous reports [9] in which heat treatment did not markedly decrease the allergenicity of OVM. On the other hand, a decrease in the pepsin/OVM ratio dramatically reduced the digestion rate, suggesting that digestibility may vary depending on the amount of OVM intake and the conditions of the individual's digestion system. In its native state, OVM possesses serine protease inhibitor activity. Fu et al. [11] and our group [10] previously reported that intact OVM was stable for 60 min in simulated intestinal fluid. Kovacs-Nolan et al. [15] also reported that pepsin-

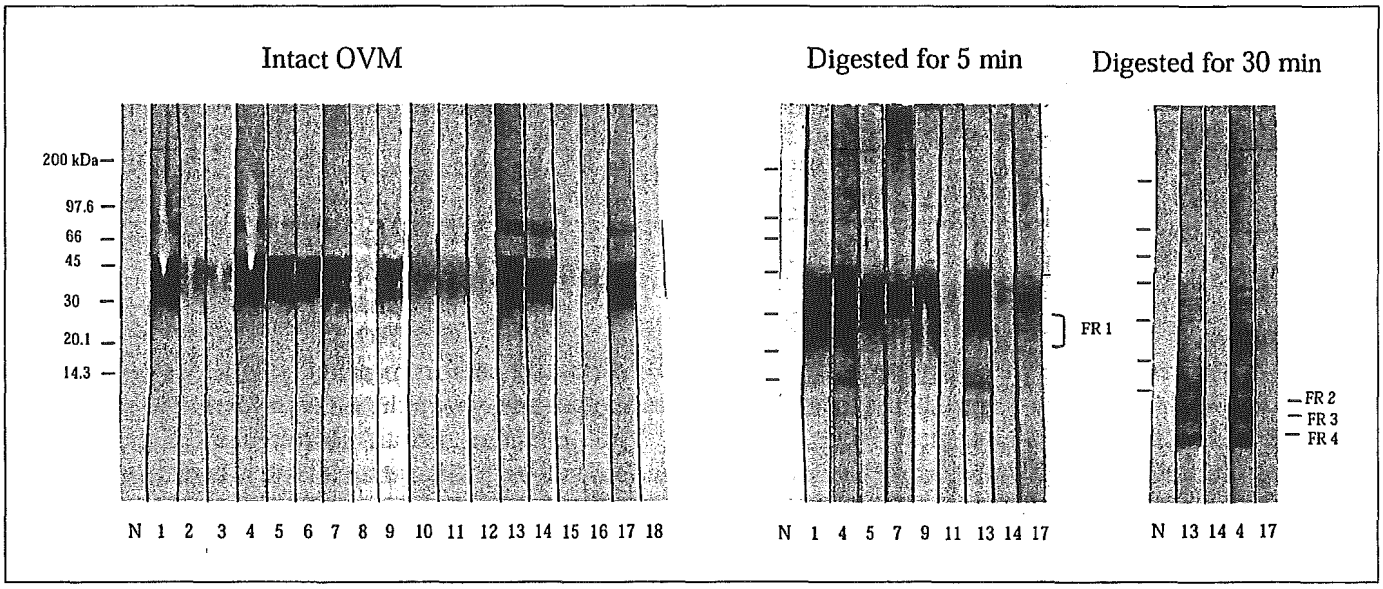

Fig. 4. Amino acid sequence and schematic representation of the SGF-digestion pattern of OVM. The amino acid sequence of OVM is shown in the upper panel. The arrows indicate the SGF-digested points according to the results of an N-terminal analysis of the OVM fragments (table 1); and the underlined regions indicate sequences identified by LC/MS/MS. Solid line = FR 1; dotted line = FR 3; dashed line = FR 4. Shaded areas represent reported human IgE epitopes [16]. The lower panel is a summary of the OVM digestion pattern according to N-terminal analysis.

Fig. 5. Western blot analysis of intact OVM and the fragments with serum IgE from egg white allergic patients and a normal volunteer. The fragments were prepared as described in the legend of figure 2. The number of each strip corresponds to the sample numbers in table 2.

digested OVM retains its trypsin inhibitor activity. Therefore, OVM and its pepsin-digested fragments were thought to be stable in the small intestine.

At a pepsin/OVM ratio of 1 unit/μg, FR 1 reached a maximum level after 2 min of digestion, while both FR 2 and FR 3 reached maximum levels after 5 min of digestion; thereafter, FR 1, FR 2, and FR 3 gradually decreased. However, FR 4 increased continuously throughout the 30-min period of digestion and the major fragments were seen after 30 min of digestion (fig. 3). FR 4 was mainly composed of three fragments whose N-terminals were 134V, 104N and 19V (table 1). A C-terminal sequence, 165N–185C, was also identified in FR 4 (table 2). These fragments contain known IgE epitopes [19] and therefore may cause allergic responses. Three of the OVM-positive sera from patients with egg white allergy reacted positively with the FR 4 fragments (table 3).

The present results are consistent with the previous finding that pediatric subjects with a higher IgE-binding activity to pepsin-treated OVM were unlikely to outgrow their egg allergy [17]. For peanut allergies, differences in IgE-binding epitopes have been reported between the patients with clinically active peanut allergies and those who developed a tolerance, regardless of the presence of high or low peanut-specific IgE levels [20].

The N-terminal residue of the major fragment (4-1) of FR 4 was Val-134 (30%; table 1). This fragment retains most of domain III, which has been reported to have significantly higher human IgG- and IgE-binding activities than those of domains I and II [12]. A domain-III OVM

variant has also been reported to cause a reduction in immunogenicity and allergenicity [21].

Domains I, II, and III contain one, three, and one N-glycosylation sites, respectively [7]. The possible relation between the carbohydrate chain in domain III and allergenicity is interesting. One report suggested that this carbohydrate chain may play an important role in allergenic determinants against human IgE antibody [13], and another report suggested that the carbohydrate chains of OVM may protect against peptic hydrolysis [22]. However, the carbohydrate moieties have been shown to have only a minor effect on allergenicity [23]. As shown in figure 2, intact OVM, FR 1, and FR 2 fragments were detected using PAS staining, suggesting the presence of carbohydrate chains, but FR 4 was not stained with the PAS reagent, despite being clearly detected with CBB. Therefore, FR 4 might contain little or no carbohydrate chains. Since FR 4 seems to maintain its allergenic potential, as described above, the absence of the carbohydrate chains in FR 4 suggests that they are not necessary for OVM allergenicity. Since the minimum peptide size capable of eliciting significant clinical symptoms of allergic reactions is thought to be 3.1 kDa [24], FR 4 may be able to trigger mast cell activation and elicit clinical symptoms.

In this report, the SGF-digestion kinetic pattern of OVM was investigated in detail, and the partial sequences of the fragments in the 4 fractions separated by SDS-PAGE were determined. Furthermore, the reactivity of the fragments with a number of serum samples from patients with egg white allergies was detected using Western blotting. The four fractions were separated according to their molecular weight and consisted of more than one fragment, as determined by N-terminal analysis. The identified sequences that started at Asn-104 and Val-134 in FR 3, as determined using LC/MS/MS (table 2), coincided with the 3-2 and 3-3 fragments in the N-terminal analysis (table 1), and the sequence that started at Asn-104 in FR 4 coincided with fragment 4-2. Moreover, the LC/MS/MS analysis indicated that FR 3 and FR 4 contained other parts of domain II and the C-terminal sequence N165–C185, which are thought to be minor components of these fractions. The combination of SGF digestion and patient IgE may provide useful information for the diagnosis and prediction of potential OVM allergenicity.

Enhancement of Hepatocyte Growth Factor-Induced Cell Scattering in *N*-Acetylglucosaminyltransferase III-transfected HepG2 Cells

Masashi HYUGA,* Sumiko HYUGA, Nana KAWASAKI, Miyako OHTA, Satsuki ITOH, Shingo NIIMI, Toru KAWANISHI, and Takao HAYAKAWA

Division of Biological Chemistry and Biologicals, National Institute of Health Sciences; 1–18–1 Kamiyoga, Setagaya-ku, Tokyo 158–8501, Japan. Received January 9, 2004; accepted March 29, 2004; published online April 1, 2004

***N*-Acetylglucosaminyltransferase III (GnT-III), which catalyzes the synthesis of a bisecting GlcNAc residue of *N*-glycans, is thought to be involved in the function of glycoproteins such as growth factor receptors. We investigated the effects of the overexpression of GnT-III on the hepatocyte growth factor (HGF) receptor c-Met, a glycoprotein, in human hepatocarcinoma HepG2 cells. GnT-III activity was elevated about 250-fold in HepG2 cells stably transfected with the GnT-III gene, whereas no significant change in GnT-III activity was observed in mock transfectants. Cell scattering assay revealed that HGF-induced cell scattering was enhanced depending on the GnT-III activities in the GnT-III transfectants. Western blot analysis and E-PHA lectin blot analysis showed that the level of c-Met protein was the same in both transfectants; however, the bisecting GlcNAc residue on c-Met was detected only in the GnT-III transfectants. Although the peak level of c-Met phosphorylation was not different in both transfectants, the level of tyrosine phosphorylation of c-Met decreased more rapidly in the GnT-III transfectants than in the mock transfectants. Furthermore, HGF-induced extracellular-regulated kinase (ERK) phosphorylation was slightly higher in the GnT-III transfectants than in the mock transfectants. These results show that overexpression of GnT-III in HepG2 cells enhances HGF-induced cell scattering, which may result from, at least in part, enhancement of HGF-induced ERK phosphorylation.**

Key words *N*-acetylglucosaminyltransferase III; cell scattering; hepatocyte growth factor; c-Met; extracellular-regulated kinase (ERK)

N-Acetylglucosaminyltransferase III (GnT-III: EC 2.4.1.144) is one of the glycosyltranferases and catalyzes the synthesis of a bisecting GlcNAc residue to the β-mannoside of the trimannose core in *N*-glycans.[1] After introduction of the bisecting GlcNAc residue to the biantennary sugar chain, further processing and elongation of *N*-glycans by the other glycosyltransferases are suppressed,[2—4] resulting in alterations of structure with reduction of size. It seems that GnT-III may affect the functions of various glycoproteins. In this respect, it is noteworthy that the overexpression of GnT-III affects receptor tyrosine kinases such as the epidermal growth factor (EGF) and NGF receptor Trk, followed by the modulation of signal transductions.[5] EGF inhibits the growth of U373 MG glioma cells, while the overexpression of GnT-III causes the decreased binding of EGF to its receptor and then autophosphorylation of the receptor, resulting in the increase in the cell growth rate.[6] In contrast, the overexpression of GnT-III in HeLaS3 cells does not affect EGF receptor autophosphorylation, but enhances internalization of the receptors, resulting in the increase of the EGF-induced phosphorylation of extracellular-regulated kinase (ERK).[7] In PC 12 cells, nerve growth factor-stimulated Trk receptor autophosphorylation and signal transduction was disrupted by the overexpression of GnT-III.[8] This evidence suggests that GnT-III may also affect the other growth factors-induced signal transduction by the modulation of the function of their receptors in some ways.

Since the expression of GnT-III is associated with many physiological and pathological processes in the liver, including its regeneration[9] and hepatocarcinogenesis,[10] it is assumed that GnT-III is involved in the processes via the modulation of some glycoproteins such as the receptor of the hepatocyte growth factor (HGF), c-Met. In the present study, we investigated the effects of the overexpression of GnT-III on the scattering of human hepatocarcinoma HepG2 cells, a defined HGF-induced biological response.

MATERIALS AND METHODS

Materials The recombinant human HGF was purchased from R&D systems (Minneapolis, MN, U.S.A.). The Dulbecco's modified Eagle's medium (DMEM), fetal calf serum (FCS), ampicillin, G418, Lipofectamine plus, and Opti-MEM were purchased from Life Technologies Inc. (Rockville, MD, U.S.A.). The human brain cDNA was purchased from Origene Technologies Inc. (Rockville, MD, U.S.A.). The mammalian expression vector pCI-neo was purchased from Promega (Madison, WI, U.S.A.). The protease inhibitors cocktail was purchased from Sigma Chemical Co (St. Louis, MO, U.S.A.). The PVDF membrane was purchased from Millipore Corporation (Bedford, MA, U.S.A.). Biotinylated E-PHA was purchased from Vector Laboratories (Burlingame, CA, U.S.A.). Protein G-immobilized magnetic beads (BioMag Protein G) were purchased from Polysciences, Inc. (Warrington, PA, U.S.A.). The anti-human c-Met antibody (C-23), anti-phospho-ERK antibody (E-4) and anti-ERK antibody (K-23) were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, U.S.A.). The monoclonal anti-phosphotyrosine antibody (PY20) was purchased from Transduction Laboratories (Lexington, KY, U.S.A.). The biotinylated anti-mouse IgG antibody, biotinylated anti-rabbit IgG antibody, peroxidase-conjugated rabbit anti-mouse IgG, and ECL chemiluminescence detection kit were purchased from Amersham-Pharmacia Biotech (Piscataway, NJ, U.S.A.). The vectastain ABC kit was purchased from Vector Laboratories (Burlingame, CA, U.S.A.). All other chemicals were obtained from commercial sources, and were of the highest purity available.

Cell Culture Human hepatocarcinoma HepG2 cells were obtained from the Japanese Cancer Research Resources Bank (Tokyo, Japan). The HepG2 cells and GnT-III gene transfectants were cultured in DMEM supplemented with 10% FCS and 0.1 mg/ml of ampicillin under a humidified atmosphere of 95% air and 5% CO_2. Following incubation for 1 d with serum-free DMEM, the cells were incubated with 50 ng/ml of HGF in serum-free DMEM.

Expression Vector Construct, Gene Transfection, and Selection of Cells The human GnT-III cDNA was amplified by PCR using human brain cDNA as a template. The cDNA fragment containing the entire coding sequence was inserted into the pCI-neo *EcoR* I site and the final construct, pCI-GnT-III, was obtained. The pCI-neo is a mammalian expression vector which includes the cytomegalovirus enhancer/promoter and the G418-resistant gene. HepG2 cells were plated in a 6-cm plastic culture dish at a density of 1×10^6 cells/ml. After 24 h, the cells were washed twice with ice-cold phosphate-buffered saline (PBS), pH 7.2, and the medium was changed to serum-free Opti-MEM. The pCI-GnT-III vector or pCI-neo vector (20 μg) was mixed with Lipofectamine plus, 100 μl of which was added to the HepG2 cells. After 5 h incubation, the medium was changed to DMEM supplemented with 10% FCS. Stable transfectants were selected using 1 mg/ml G418.

GnT-III Activity The GnT-III activity was measured according to the methods described previously.[11] Briefly, cell pellets were homogenized in ice-cold PBS containing protease inhibitors, and the supernatant was obtained after removal of the nucleus fraction by centrifugation for 20 min at $900\times g$. The GnT-III activity in the supernatant was assayed by high performance liquid chromatography methods using the fluorescence-labeled sugar chain (GlcNAcβ-1, 2-Manα-1, 6-[GlcNAcβ-1, 2-Manα-1, 3-] Manβ-1, 4-GlcNAcβ-1, 4-GlcNAc-pyridylamino) as a substrate. The substrate was prepared according to the method of Tokugawa *et al.*[12]

Cell Scattering Assay The HepG2 cells were plated in a 6-cm plastic culture dish at a density of 5×10^4 cells/ml. The HepG2 cells were allowed to grow as discrete colonies for 2—3 d. The culture medium was then replaced with fresh DMEM medium containing 50 ng/ml HGF. After 24 h, the cells were observed under a phase contrast microscope.

Immunoprecipitation and Western Blot Analysis The cultured cells were washed twice with ice-cold PBS and disrupted in the lysis buffer (20 mM Tris, pH 7.2, 1% Triton X-100, 10% glycerol, 1 mM APMSF, 5 mM aprotinin, 1 mM sodium orthovanadate, 10 mM sodium fluoride, and 10 mM iodoacetamide). The protein concentrations were determined using a protein assay kit (Bio-Rad, CA, U.S.A.). The cell-free lysates (1 mg) were immunoprecipitated with the anti-human c-Met antibody and protein G-immobilized magnetic beads (BioMag Protein G). For Western blot analysis, whole cell lysates or immunoprecipitates were subjected to 6 or 10% sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions, and then transferred to a PVDF membrane. The blot was blocked with 1% bovine serum albumin (BSA) in Tris-buffered saline containing 0.1% Tween 20 (TBST). For the detection of c-Met, the blot was incubated with anti-human c-Met antibody, and biotinylated anti-rabbit IgG antibody. For the detection of the phosphorylated tyrosine residues of c-Met, the blot was incubated with a monoclonal anti-phosphotyrosine antibody, and peroxidase-conjugated rabbit anti-mouse IgG. For the detection of phosphorylated ERK1/2, the blot was incubated with anti-ERK antibody, and biotinylated anti-mouse IgG antibody. Biotinylated antibody was detected using a Vectastain ABC-kit, and the blots were developed using the ECL chemiluminescence detection kit according to the manufacturer's instructions.

Lectin Blot Analysis Immunoprecipitated c-Met were subjected to 6% SDS-PAGE and transferred to PVDF membranes, as described above. The blot was blocked with 1% BSA in TBST and then incubated with 1 μg/ml biotinylated erythroagglutinating phytohemagglutinin (E-PHA) in TBST for 1 h at room temperature. After washing with TBST, the lectin-reactive proteins were detected using a Vectastain ABC kit and the ECL chemiluminescence detection kit.

RESULTS

Establishment of HepG2 Cell Lines Stably Expressing GnT-III The GnT-III expression vector pCI-GnT-III was transfected into the HepG2 cells. The G418-resistant cells were screened as candidates of the GnT-III transfectants. Two randomly selected G418-resistant clones were evaluated for GnT-III activity. The clones expressing moderately and highly were designated HepG2-IIIm and HepG2-IIIh, respectively. A pCI-neo vector transfectant, designated as HepG2-mock, was also established as a negative control. The GnT-III activity in the HepG2-IIIm and HepG2-IIIh cells was significantly elevated about 20- and 250-fold, respectively, whereas the activity in the HepG2-mock cells did not differ significantly among the parental HepG2 cells (Table 1).

Enhancement of HGF-Induced Cell Scattering in GnT-III Transfectants To determine the effect of the overexpression of GnT-III on the HGF-induced cell scattering, the GnT-III transfectants and mock transfectants were examined. When the HepG2-mock cells were cultured, they showed a cobble-stone shape and had formed colonies of the cells (Fig. 1A). No significant difference in cell morphology of the GnT-III transfectants was observed (Figs. 1B, C). HepG2-mock cells scattered following cell-cell dissociation by the stimulation with HGF (Fig. 1D). The cell scattering of the GnT-III transfectants was more pronounced than the HepG2-mock cells; the enhancement of cell scattering was most pronounced in the HepG2-IIIh cells that had a high GnT-III activity (Figs. 1E, F).

Analysis of c-Met of GnT-III Transfectants The expression levels of the c-Met protein in GnT-III transfectants were analyzed by Western blot analysis. No significant change of the level of c-Met was observed (Fig. 2). To analyze the alterations of the *N*-glycan structure on c-Met, E-

Table 1. Enzyme Activities of GnT-III in Mock- and GnT-III Transfected HepG2 Cells

Cell line	GnT-III activity [pmol/h/mg protein]
HepG2	79±30
HepG2-mock	149±50
HepG2-IIIm	1400±260
HepG2-IIIh	19600±1350

Data were mean±S.E. of three separate experiments.

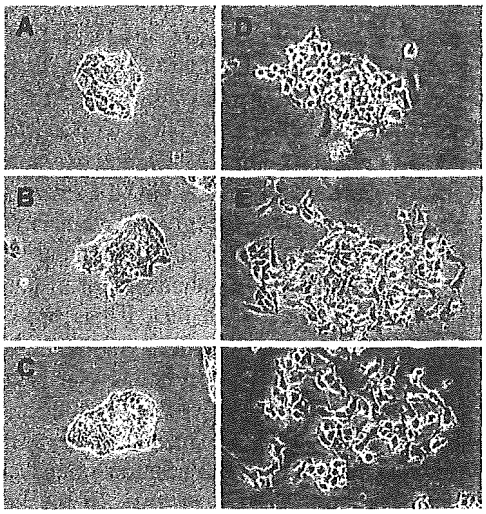

Fig. 1. HGF-Induced Cell Scattering in HepG2-Mock Cells and GnT-III Transfected HepG2 Cells

HepG2 mock-cells (A, D), HepG2-IIIm cells (B, E), and HepG2-IIIh cells (C, F) were cultured with (D, E, F) or without (A, B, C) HGF (50 ng/ml) for 24 h. Representative fields were photographed using a phase-contrast microscope.

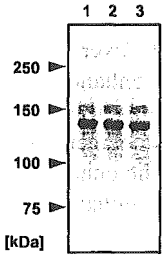

Fig. 2. Western Blot Analysis of c-Met

Total cell lysates from HepG2-mock cells (lane 1), HepG2-IIIm cells (lane 2), and HepG2-IIIh cells (lane 3) were subjected to 6% SDS-PAGE and then transferred to PVDF membrane. The blots were probed with anti-c-Met antibody.

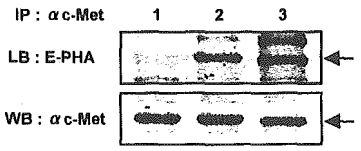

Fig. 3. Lectin Blot Analysis of c-Met

C-Met was immunoprecipitated from cell lysates of HepG2-mock cells (lane 1), HepG2-IIIm cells (lane 2), and HepG2-IIIh cells (lane 3). Immunoprecipitates were subjected to 6% SDS-PAGE and then transferred to PVDF membrane. The blots were probed with E-PHA (upper panel) or anti-c-Met antibody (lower panel). Arrows indicate c-Met.

PHA lectin blot analysis was performed. E-PHA binds specifically to bisecting GlcNAc residues.[13] Immunoprecipitated c-Met from the HepG2-IIIm cells and the HepG2-IIIh cells showed significant reactivity of E-PHA (Fig. 3), showing that *N*-glycan on c-Met was modified with bisecting GlcNAc residues. It was noted that the apparent molecular size of c-Met from the HepG2-IIIh cells were smaller than that from the HepG2-mock cells. The following experiments were performed with HepG2-IIIh cells and HepG2-mock cells.

Tyrosine Phosphorylation of c-Met in Gn T-III Transfectants To determine the effect of the GnT-III transfection on HGF signaling, HGF-induced tyrosine phosphorylation of

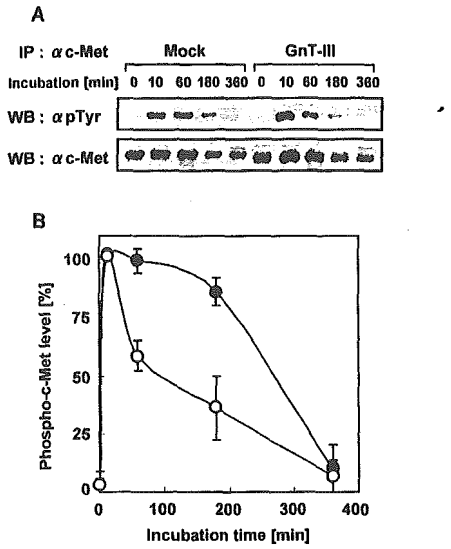

Fig. 4. The Time Course of the Tyrosine Phosphorylation of c-Met

(A) Cells were harvested at the indicated time after HGF treatment (50 ng/ml). C-Met, immunoprecipitated from the cell lysates of HepG2-mock cells (●) and HepG2-IIIh cells (○) were subjected to 6% SDS-PAGE and then transferred to a PVDF membrane. The blot was probed with anti-phosphotyrosine antibody (upper panel) or anti-human c-Met antibody (lower panel). One representative result of three separate experiments is shown. (B) The intensities of the bands obtained with phosphorylated c-Met were normalized to the intensities of the c-Met bands. These values are shown as percentages of the level of c-Met phosphorylation in HepG2-mock cells treated with HGF for 10 min (mean±S.E., three separate experiments).

c-Met in HepG2-IIIh cells and HepG2-mock cells were examined. The c-Met phosphorylation level reached a peak by 10 min after the HGF treatment in each transfectant. Although no difference in the peak level of c-Met phosphorylation between the HepG2-IIIh cells and HepG2-mock cells was observed, the level of c-Met phosphorylation in the HepG2-IIIh cells was reduced more rapidly than in the HepG2-mock cells (Fig. 4).

ERK Activation in GnT-III Transfectants To further clarify the effect of the GnT-III transfection on HGF signaling, the HGF-induced phosphorylation of ERK in the HepG2-IIIh cells and HepG2-mock cells was also examined. The time course of the tyrosine phosphorylation of ERK showed that the phosphorylated ERK level reached a peak by 10 min after treatment in each transfectant. The peak level in the HepG2-IIIh cells was slightly higher than in the HepG2-mock cells (Fig. 5).

DISCUSSION

In this paper we investigated the effects of the overexpression of GnT-III on the scattering of human hepatocarcinoma HepG2 cells, a defined HGF-induced biological response, since the function of the HGF receptor c-Met could be modulated by GnT-III transfection followed by the alteration of its biological functions, as described in the "INTRODUCTION" section. The results showed that GnT-III gene transfection increases GnT-III activity by about 250 fold, followed by a significant increase of E-PHA reactivity with c-Met (Fig. 3), indicating that the transfection of GnT-III increased the amount of bisecting oligosaccharide residue on c-Met. In addition, the molecular size of c-Met in the HepG2-IIIh cells was smaller than that in the HepG2-mock cells (Figs. 2, 3), suggesting that an elongation of *N*-glycans on c-Met was

suppressed by the bisecting GlcNAc residue. The same observation has been shown in various glycoproteins such as the EGF receptor,[7] E-cadherin,[14,15] and CD44.[16]

We investigated the effect of the overexpression of GnT-III on HGF-induced cell scattering using these transfectants, because cell scattering is one of the HGF-induced biological responses and an important component of several physiological and pathological processes. We found that HGF-induced cell scattering in the GnT-III transfectants was enhanced depending on the GnT-III activities. As far as we know, this is the first report of the enhancing effect of HGF-induced cell scattering by the overexpression of GnT-III.

To confirm the effect of GnT-III overexpression on HGF signaling, we first investigated the effect on the HGF-induced tyrosine phosphorylation of c-Met in GnT-III transfectants. Unexpectedly, the peak level of the tyrosine phosphorylation of c-Met did not change by GnT-III. In addition, the level of c-Met phosphorylation was reduced quite a bit more rapidly than that in the HepG2-mock cells. Previous studies shown that HGF stimulation also leads to down-regulation of the receptor.[17] We assume that the rapid dephosphorylation was caused by up-regulated HGF signaling.

We further examined the effects on the HGF-induced phosphorylation of ERK, because ERK activation is associated with HGF-induced cell scattering.[18] The ERK phosphorylation was slightly enhanced by the GnT-III overexpression, showing that the enhancement of cell scattering involves the up-regulation of the HGF-induced ERK phosphorylation. The mechanisms by which GnT-III overexpression affects ERK activation is now under investigation. It has been shown that GnT-III overexpression enhances the EGF-induced ERK phosphorylation in HelaS3 cells by up-regulation of the internalization rate of the receptors.[7] A possible mechanism by which GnT-III overexpression enhances HGF-induced ERK phosphorylation is that GnT-III affects c-Met internalization.

In this study, we demonstrated that GnT-III overexpression increased the amount of bisecting oligosaccharide structures and shortened the *N*-glycans associated with c-Met. Lectin blot analysis of total showed that *N*-glycans of the other glycoproteins were also changed by GnT-III overexpression (data not shown). Therefore, the glycoproteins involved in cell scattering, such as E-cadherin and integrin, are candidate proteins for involvement in the enhancement of cell scattering by GnT-III overexpression. In fact, it has been reported that GnT-III overexpression affects their biological functions.[14,15,19] Further study is needed to clarify the mechanism involved in the enhancement of cell scattering.

In evaluating the significance of the present results, it seems worthwhile to examine the relation of the change of GnT-III with the action of HGF *in vivo*. In the normal rat liver, GnT-III activity is very low. However, the activity increased about 4-fold in regenerating rat liver.[9] HGF is induced in regenerating rat liver, and stimulates hepatocyte growth. In addition, it was shown that hepatocarcinoma exhibited a high level of GnT-III activity, whereas normal liver contains very little.[20] Autocrine HGF signaling leads to abnormal malignant progression.[21] Therefore, the increase of GnT-III may contribute to liver regeneration and hepatocarcinoma progression by the enhanced HGF signal.

In conclusion, we demonstrated that the overexpression of GnT-III caused the enhancement of HGF-induced cell scattering, and suggest that the enhancement of cell scattering involves, at least in part, enhancement of the HGF-induced ERK phosphorylation.

Abstract

Follistatin (FS), a glycoprotein, plays an important role in cell growth and differentiation through the neutralization of the biological activities of activins. In this study, we analyzed the glycosylation of recombinant human FS (rhFS) produced in Chinese hamster ovary cells. The results of SDS-PAGE and MALDI-TOF MS revealed the presence of both non-glycosylated and glycosylated forms. FS contains two potential *N*-glycosylation sites, Asn95 and Asn259. Using mass spectrometric peptide/glycopeptide mapping and precursor-ion scanning, we found that both *N*-glycosylation sites were partially glycosylated. Monosaccharide composition analyses suggested the linkages of fucosylated bi- and triantennary complex-type oligosaccharides on rhFS. This finding was supported by mass spectrometric oligosaccharide profiling, in which the *m/z* values and elution times of some of the oligosaccharides from rhFS were in good agreement with those of standard oligosaccharides. Site-specific glycosylation was deduced on the basis of the mass spectra of the glycopeptides. It was suggested that biantennary oligosaccharides are major oligosaccharides located at both Asn95 and Asn259, whereas the triantennary structures are present mainly at Asn95.

1. Introduction

Follistatin (FS), a glycoprotein, was first discovered in ovarian follicular fluid as an inhibitor of pituitary follicle-stimulating hormone secretion [1,2]. Subsequent studies have revealed that FS can bind to activins and neutralize their biological activities [3,4]. Activins are members of the transforming growth factor-β superfamily, and they play important roles in the regulation of cell growth and in the differentiation processes that lead to morphogenesis in early vertebrate development [5,6]. Since FS and activins are broadly distributed, they are not confined solely to tissues associated with reproduction [7].

FS is present in heterogeneous forms [8]. The FS gene consists of 315 amino acids, and it includes six exons (Fig. 1); alternative splicing can generate two isoforms, i.e. a 315-amino-acid protein (the full-length form, FS315) and a 288-amino-acid protein (the carboxy-truncated form, FS288) [9]. The activin-neutralizing activity of FS288 is higher than that of FS315 [10,11], which appears to correlate with their heparin/heparan sulfate proteoglycan-binding abilities [12]. The heterogeneity of FS is also due to diverse glycosylation. FS has two potential *N*-glycosylation sites (Asn95 and Asn259). Oligosaccharides are generally known to play important roles in defining the properties of glycoproteins such as their biological activity, immunogenicity,
