with a four-amino acid mutation of the AB loop (R412S, A415G, E416G, and K417G), the Ad type 35 fiber shaft, and a deletion of the RGD motif of the penton base. Ad/ΔF(FG)ΔP-S35-L2, which is identical to Ad/ΔFΔP-S35-L2 in our previous report (Koizumi *et al.*, 2003a), contains the Ad type 5 fiber knob with a four-amino acid deletion of the FG loop (T489, A490, Y491, and T492), the Ad type 35 fiber shaft, and deletion of the RGD motif of the penton base. Ad/ΔF(AB)ΔP-S35-RGD-L2 contains an RGD motif in the HI loop of the fiber knob in Ad/ΔF(AB)ΔP-S35-L2. Ad-L2 is a conventional Ad vector. All mutations of the mutant Ad vectors and possible interaction of each virus with the cells are summarized in Table 1 and Fig. 1A. All of the mutant Ad vectors used in this study were readily propagated with particle titers similar to that of the conventional Ad vector, Ad-L2 (see Materials and Methods).

To confirm the modification of the fiber protein in each Ad vector, Western blot analysis against fiber protein was performed with rabbit fiber knob polyclonal antibody (Fig. 1B). The mutant fiber and wild-type fiber are easily distinguished because the mutant fiber is smaller than the wild-type fiber because of the small size of the Ad type 35 fiber shaft and because Ad/ΔF(AB)ΔP-S35-L2 has a fiber protein four amino acids longer than that of Ad/ΔF(FG)ΔP-S35-L2. Western blot analysis shows the expected size of the fiber proteins, suggesting that each Ad vector should indeed contain the expected fiber protein.

Gene transfer in vitro

We examined the gene transfer activity in SK HEP-1 cells transduced with Ad/ΔF(AB)ΔP-S35-L2 in comparison with

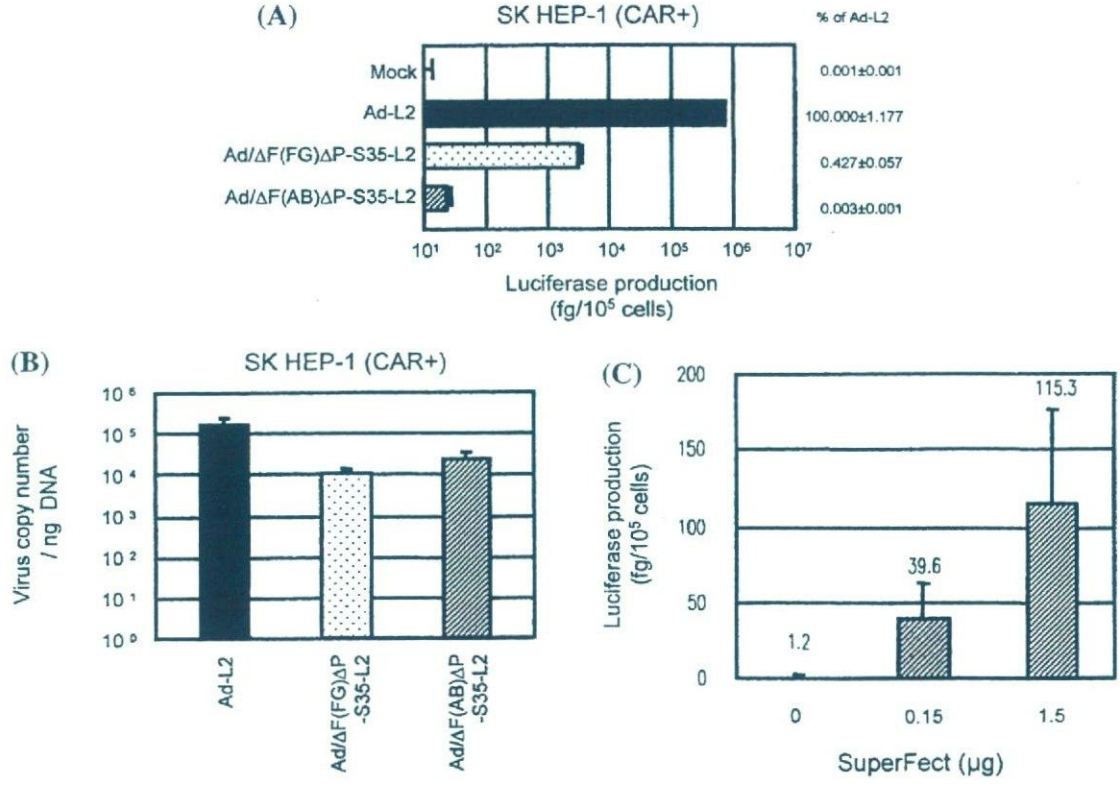

FIG. 2. Luciferase production and viral uptake in SK HEP-1 cells transduced with several Ad vectors. (**A**) Comparison of luciferase production in human cells transduced with Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2. SK HEP-1 cells were transduced with Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 (3000 VP/cell) for 1.5 hr. After culture for 48 hr, luciferase production in the cells was measured by luminescence assay. Data are expressed as means ± SD ($n = 4$). Relative levels of luciferase expression are described by designating the value of Ad-L2 as 100. (**B**) Viral uptake in SK HEP-1 cells. SK HEP-1 cells were transduced with Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 at 3000 VP/cell. After culture for 1.5 hr, the cells were washed with PBS, resuspended in 0.05% trypsin–0.5 m*M* EDTA–PBS solution, and incubated at 37°C for 10 min. After this incubation, the cells were incubated at 37°C for 10 min with 0.05% DNase I–0.5 *M* $MgCl_2$–PBS, washed with PBS, and resuspended in 0.1 *M* EDTA–PBS solution. The amounts of Ad genome DNA isolated from the cells were quantified with the TaqMan fluorogenic detection system. Data are expressed as means ± SD ($n = 4$). (**C**) Comparison of luciferase production in SK HEP-1 cells transduced with a complex of Ad/ΔF(AB)ΔP-S35-L2 and SuperFect. SK HEP-1 cells (2×10^4 cells) were seeded into a 24-well dish. The next day, the cells were either not transduced or were transduced with a complex of Ad/ΔF(AB)ΔP-S35-L2 and SuperFect (0.15 or 1.5 μg) (Qiagen) for 1.5 hr. After culture for 48 hr, luciferase production in the cells was measured with a luciferase assay system. Data are expressed as means ± SD ($n = 4$).

Ad/ΔF(FG)ΔP-S35-L2 or Ad-L2 (Fig. 2). SK HEP-1 cells express both CAR and α_v integrin (Koizumi *et al.*, 2001, 2003b). To measure the internalization of Ad particles into the cells, Ad genome DNA in the cells after 1.5 hr of transduction with each Ad vector was also quantified with the TaqMan fluorogenic detection system. Viral particles associated with the cellular surface were removed by trypsin–EDTA–PBS and DNase I–$MgCl_2$–PBS treatment as described in Materials and Methods. Cells transduced with Ad/ΔF(AB)ΔP-S35-L2 showed much lower luciferase production than those transduced with Ad/ΔF(FG)ΔP-S35-L2. Ad/ΔF(AB)ΔP-S35-L2 mediated only approximately 0.003% of the luciferase production of Ad-L2, whereas Ad/ΔF(FG)ΔP-S35-L2 mediated approximately 0.42% of that of Ad-L2 (Fig. 2A). In contrast, the amounts of Ad/ΔF(AB)ΔP-S35-L2 DNA and Ad/ΔF(FG)ΔP-S35-L2 DNA in SK HEP-1 cells were only 10-fold lower than those of Ad-L2 DNA. The amounts of Ad/ΔF(AB)ΔP-S35-L2 DNA in the cells were similar to those of Ad/ΔF(FG)ΔP-S35-L2 DNA (Fig. 2B).

Because Ad/ΔF(AB)ΔP-S35-L2 showed extremely low transduction activity, we examined luciferase production in SK HEP-1 cells transduced with Ad/ΔF(AB)ΔP-S35-L2 in the presence of SuperFect (polyamidoamine dendrimer reagent; Qiagen). Ad/ΔF(AB)ΔP-S35-L2 mediated high levels of luciferase production in a dose-dependent manner with SuperFect (Fig. 2C). Therefore, low luciferase production by Ad/ΔF(AB)ΔP-S35-L2 is likely due to a lack of specific binding activity between the virus and target cells and to endosomal escape, but it was not due to the virus being defective. These results suggest that the abolishment of CAR, integrin, and HSG binding of Ad vectors significantly reduces transduction efficiency and that the four-amino acid mutation of the AB loop of the fiber knob reduces transduction to a greater extent than does the four-amino acid deletion of the FG loop of the fiber knob.

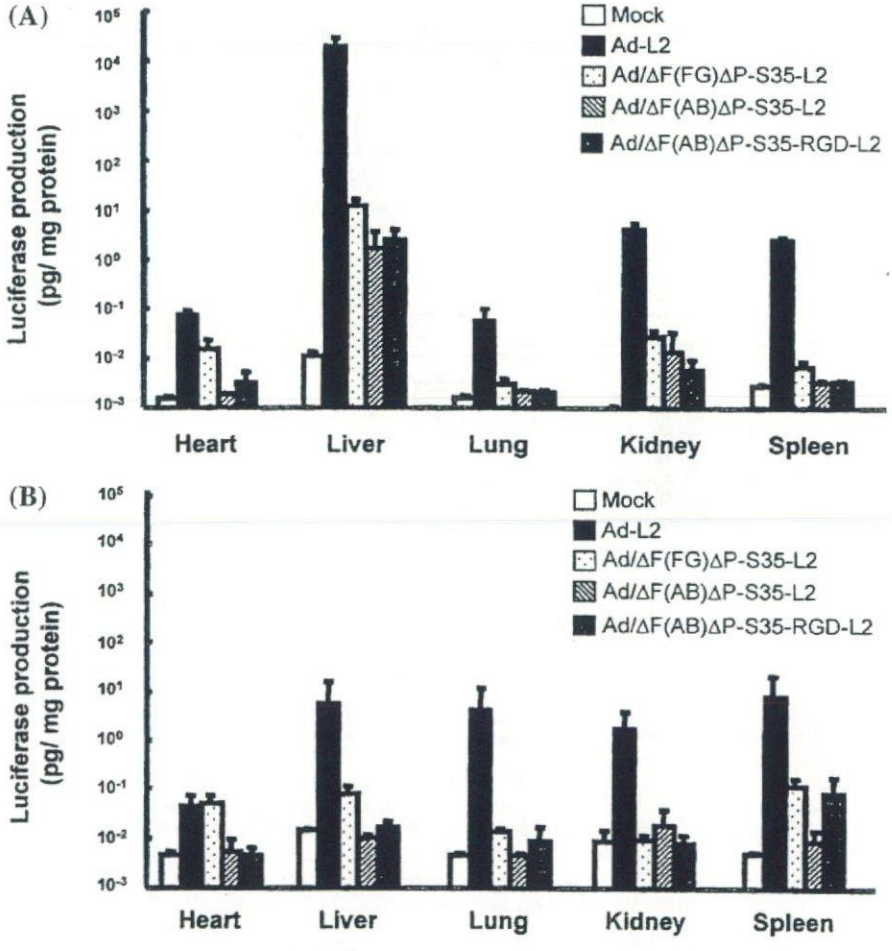

FIG. 3. Luciferase production in mice after systemic administration of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-RGD-L2. Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, Ad/ΔF(AB)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-RGD-L2 was (**A**) intravenously (3.0×10^{10} VP) or (**B**) intraperitoneally (1.0×10^{11} VP) injected into mice. Forty-eight hours later, the heart, lung, liver, kidney, and spleen were harvested and luciferase production was measured by a luciferase assay system. All data represent the means ± SD of four to six mice.

Gene transfer in vivo

Next, to examine whether natural Ad tropism to tissues, including liver, can be more suppressed by Ad/ΔF(AB)ΔP-S35-L2 in comparison with Ad/ΔF(FG)ΔP-S35-L2, each Ad vector was administered to mice by either intravenous (3.0×10^{10} VP) or intraperitoneal (1.0×10^{11} VP) injection, and luciferase production in the organ was measured (Figs. 3 and 4). In the case of intraperitoneal injection, a high dose of Ad vector (1.0×10^{11} VP) was injected because luciferase production was not detected in mouse tissue after intraperitoneal injection of 3.0×10^{10} VP of either Ad/ΔF(FG)ΔP-S35-L2 or Ad/ΔF(AB)ΔP-S35-L2. With intravenous injection, Ad/ΔF(AB)ΔP-S35-L2 mediated approximately 15,000-fold lower liver transduction than Ad-L2, and resulted in approximately 10-fold lower liver transduction compared with Ad/ΔF(FG)ΔP-S35-L2 (Fig. 3A). A similar pattern was observed in the heart, lung, kidney, and spleen, although the absolute levels of luciferase production were much lower compared with those in the liver.

With intraperitoneal injection, Ad-L2 mediated similar levels of luciferase production in the liver, lung, kidney, and spleen (Fig. 3B). The suppressive pattern of luciferase production in each organ after intraperitoneal injection of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 was similar to that after intravenous injection. Ad/ΔF(AB)ΔP-S35-L2 showed much more reduced luciferase production in the organs than did Ad/ΔF(FG)ΔP-S35-L2 (Fig. 3B). Luciferase production in each organ after intraperitoneal injection of Ad/ΔF(AB)ΔP-S35-L2 was at almost background levels. These results indicate that the triple-mutant Ad vector containing a mutation of the AB loop of the fiber knob exhibits much lower luciferase production than does the triple-mutant Ad vector containing a mutation of the FG loop of the fiber knob, in both intravenously and intraperitoneally injected mice.

Distribution of Ad vectors after systemic administration

To examine the biodistribution of Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad-L2 in mice at a early stage after intravenous (3×10^{10} VP) and intraperitoneal (1×10^{11} VP) injection, the amounts of Ad DNA in organs 3 hr after Ad vector injection were measured with the TaqMan fluorogenic detection system. The amounts of Ad DNA in organs after intravenous injection showed no significant difference among mice injected with Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad-L2 (Fig. 4A), although the amounts of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 in the kidney were less than that of Ad-L2. In the case of intraperitoneal injection, Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 showed higher or similar amounts of Ad DNA in the liver or spleen, respectively, than Ad-L2 (Fig. 4B).

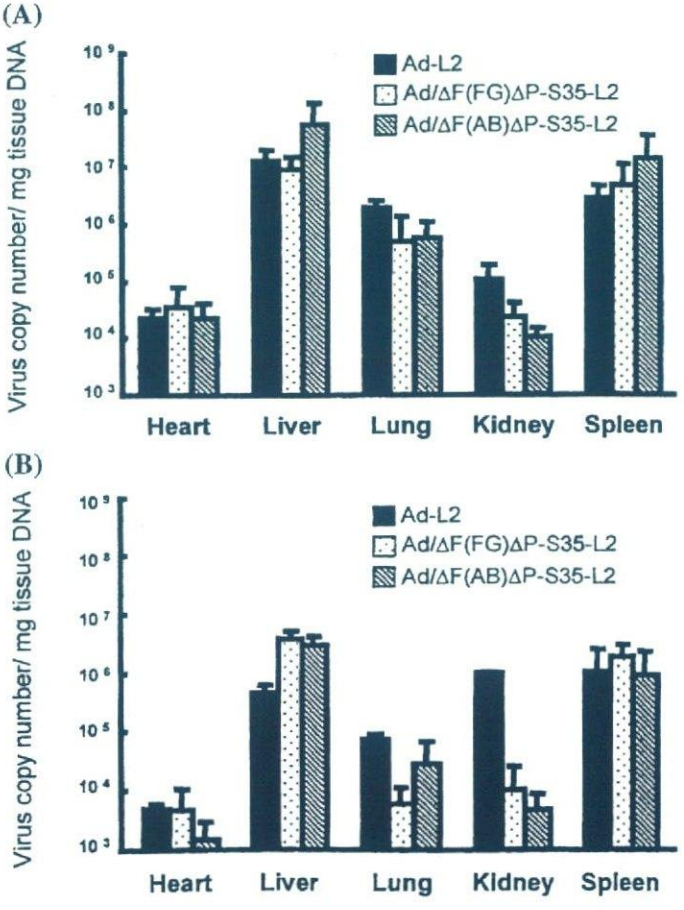

FIG. 4. Biodistribution of viral DNA after systemic administration of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 into mice. Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 was (**A**) intravenously (3.0×10^{10} VP) or (**B**) intraperitoneally (1.0×10^{11} VP) injected into mice. Three hours later, the heart, lung, liver, kidney, and spleen were harvested and Ad vector DNA was measured with the quantitative TaqMan PCR assay. All data represent the means ± SD of four to six mice.

Less Ad/ΔF(AB)ΔP-S35-L2 accumulated in the heart, lung, and kidney compared with Ad-L2. The data regarding luciferase production (Fig. 3) and the amounts of Ad DNA in most organs, especially the liver (Fig. 4), showed discrepancies in the cases of both intravenous and intraperitoneal injection.

Amounts of Ad vector DNA in liver parenchymal and nonparenchymal cells

Next, to examine why there is an especially large difference between luciferase production and Ad DNA accumulation in the liver, the amounts of Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad-L2 delivered to parenchymal cells (PCs; hepatocyte) and nonparenchymal cells (NPCs; Kupffer cells and endothelial cells) 3 hr after injection were measured with the TaqMan fluorogenic detection system (Fig. 5). In the case of intravenous injection of Ad vector at 3×10^{10} VP, more Ad-L2 DNA was found in PCs than in NPCs, whereas there was less Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 DNA in PCs than in NPCs (Fig. 5A). This finding is consistent with our previous reports based on analysis by semiquantitative PCR (Koizumi *et al.*, 2003a). In the case of intraperitoneal injection of Ad vector at 1×10^{11} VP, Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad-L2 DNA accumulated more in NPCs than in PCs (Fig. 5B). Thus, lower luciferase production in the liver after intravenous and intraperitoneal injection of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 would be partly due to higher accumulation of vectors in NPCs. The NPCs might take up Ad via phagocytosis and resolve viral DNA, resulting in lower gene expression.

Blood clearance of Ad vectors

To examine the biodistribution in more detail, the blood clearance rates of Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad-L2 in mice were measured with the TaqMan fluorogenic detection system (Fig. 6). In the case of intravenous injection, blood clearance curves for Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad-L2 were similar, and all the vectors showed rapid decrease from the bloodstream (Fig. 6A). In the case of intraperitoneal injection, Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 showed similar blood clearance curves. The amounts of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 DNA were approximately 10-fold higher than those of Ad-L2 DNA between 60 and 120 min after injection (Fig. 6B). The area under the curve ($AUC_{2\text{-}180}$) values of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 were 5- to 7-fold higher than that of Ad-L2 (data not shown). Higher levels of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 were found to be introduced into the bloodstream from the intraperitoneum than Ad-L2.

Liver serum enzymes and serum interleukin-6 levels after administration of Ad vector

Systemic administration of Ad vectors results in the initiation of inflammation and strong innate immunity responses in animals and humans (Schnell *et al.*, 2001; Muruve, 2004), and this toxicity limits the utility of Ad vectors for gene therapy. To evaluate the toxicity of each Ad vector, we measured the levels of AST, ALT, and IL-6 in serum after systemic administration. After injection of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 in mice (both by intravenous and intraperitoneal injection), the levels of AST and ALT in serum were similar to those in nontreated mice, suggesting that Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 did not show liver toxicity (Fig. 7). In contrast, Ad-L2 led to high levels of AST and ALT in serum after intravenous injection (Fig. 7A). In the case of IL-6, neither intravenous nor intraperitoneal injection of Ad/ΔF(AB)ΔP-S35-L2 or Ad/ΔF(FG)ΔP-S35-L2 mediated IL-6 production, whereas injection of Ad-L2 led to high levels of IL-6 in serum (Fig. 8). These results suggest that Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 show less liver toxicity and innate immunity reaction (IL-6 production) after systemic administration.

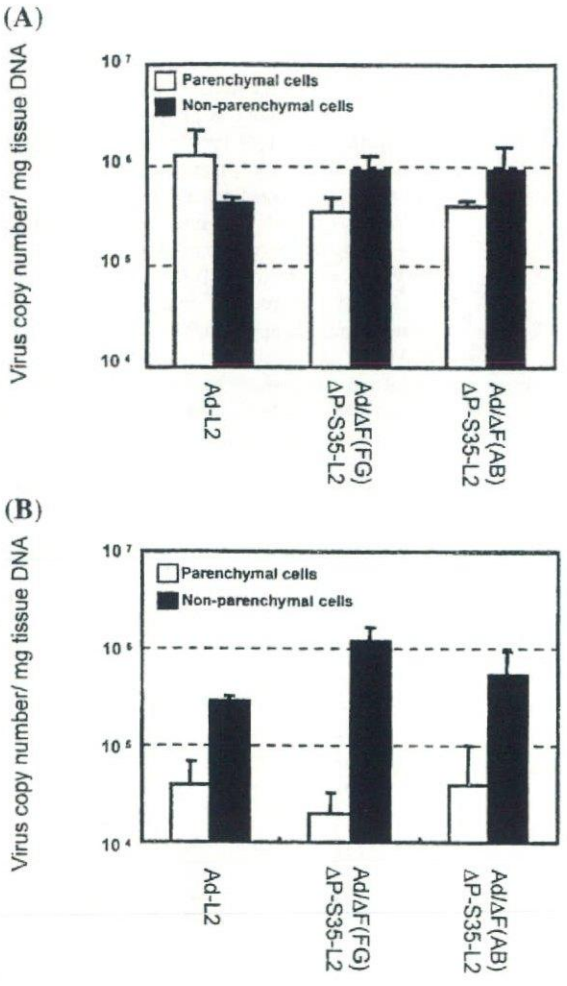

FIG. 5. Biodistribution of viral DNA in liver parenchymal and nonparenchymal cells. Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 was (**A**) intravenously (3.0×10^{10} VP) or (**B**) intraperitoneally (1.0×10^{11} VP) injected into mice. Collagenase perfusion was performed 3 hr after injection of Ad vector to separate liver PCs and NPCs. Total DNA, including Ad vector DNA, was isolated from the cells, and Ad vector DNA was measured by quantitative TaqMan PCR assay. All data represent the means ± SD of four to six mice.

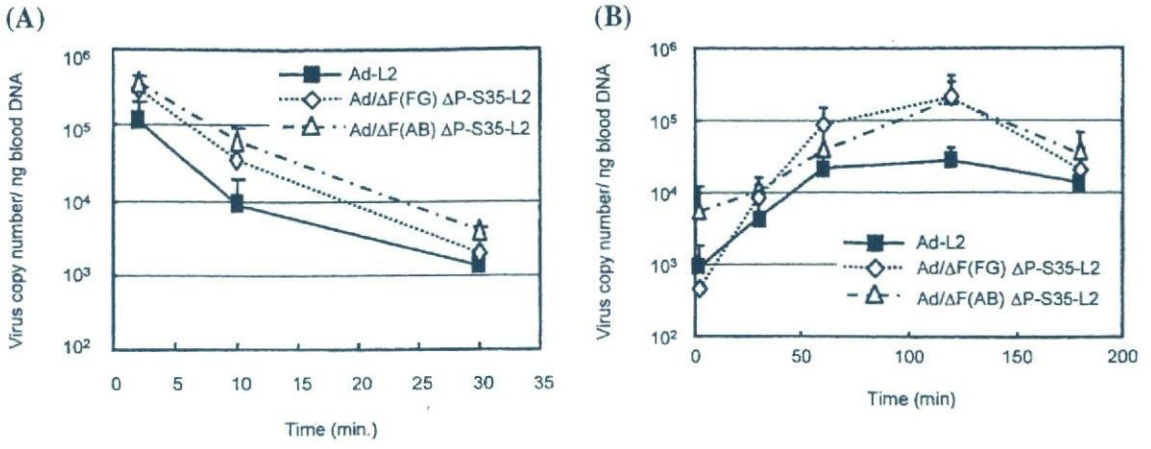

FIG. 6. Blood clearance of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, and Ad/ΔF(AB)ΔP-S35-L2 after systemic administration into mice. Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 was (**A**) intravenously (3.0×10^{10} VP) or (**B**) intraperitoneally (1.0×10^{11} VP) injected, and blood was drawn by retroorbital bleeding at the indicated times postinjection. Total DNA, including Ad vector DNA, was isolated from the blood, and Ad vector DNA was measured by quantitative TaqMan PCR assay. All data represent the means ± SD of four to six mice.

Inclusion of RGD ligand into the fiber knob in triple-mutant Ad vectors

For the development of a targeted Ad vector, addition of foreign ligands into a viral capsid that no longer infects cells is required. For this purpose, Ad/ΔF(AB)ΔP-S35-RGD-L2, in which the RGD peptide was introduced into the HI loop of the fiber knob of Ad/ΔF(AB)ΔP-S35-L2, was constructed, and gene transfer activity was measured in SK HEP-1 cells (Fig. 9A). Ad/ΔF(AB)ΔP-S35-RGD-L2 showed 100-fold higher luciferase production in SK HEP-1 cells than did Ad/ΔF(AB)ΔP-S35-L2 (Fig. 9A). In the inhibition experiment using RGD peptide, luciferase production in cells transduced with Ad/ΔF(AB)ΔP-S35-RGD-L2 was suppressed by RGD peptide in a dose-dependent fashion, suggesting that Ad/ΔF(AB)ΔP-S35-RGD-L2 mediates gene transfer through RGD peptides in the fiber knob (Fig. 9B).

Next, to examine whether Ad/ΔF(AB)ΔP-S35-RGD-L2 mediates luciferase production *in vivo* in a manner different from Ad/ΔF(AB)ΔP-S35-L2, Ad/ΔF(AB)ΔP-S35-RGD-L2 was administered to mice by either intravenous (3.0×10^{10} VP) or intraperitoneal (1.0×10^{11} VP) injection, and luciferase production in organs was measured (Fig. 3). Data suggest that addition of RGD peptide to the triple-mutant Ad vector does not change the biodistribution *in vivo*, although intraperitoneal injection of Ad/ΔF(AB)ΔP-S35-RGD-L2 mediated slightly higher luciferase production in the spleen compared with Ad/ΔF(AB)ΔP-S35-L2.

DISCUSSION

In this study, we generated a new Ad vector with a four-amino acid mutation of the AB loop in the fiber knob (T489, A490, Y491, and T492), deletion of the RGD motif of the penton base, and substitution of the fiber shaft domain for that derived from Ad type 35, and demonstrated that this triple-mutant Ad vector shows significantly lower gene transfer activity (both *in vitro* and *in vivo*). The triple-mutant Ad vector containing a mutation of the AB loop in the fiber knob mediated much lower gene transfer activity than the previously generated triple-mutant Ad vector containing a mutation of the FG loop in the fiber knob (Koizumi *et al.*, 2003a). Furthermore, the triple-mutant Ad vector was less toxic, and showed almost background levels of both liver serum enzymes (AST and ALT) and IL-6 in mouse serum.

Ad vectors show nonspecific tissue distribution after *in vivo* gene transfer. This distribution is due largely to the relatively broad expression of CAR, α_v integrin, and HSGs; the size of sinusoidal fenestrae (Fechner *et al.*, 1999; Lievens *et al.*, 2004); and the complement system (Zinn *et al.*, 2004). To generate targeted Ad vectors, several groups have reported CAR binding-ablated Ad vectors with an AB or FG loop mutation of the fiber knob (Bewley *et al.*, 1999; Kirby *et al.*, 1999; Asaoka *et al.*, 2000; Alemany and Curiel, 2001; Einfeld *et al.*, 2001; Leissner *et al.*, 2001; Mizuguchi *et al.*, 2002; Smith *et al.*, 2002). However, there has been no report on the difference in gene transfer activity (*in vitro* and *in vivo*) between Ad vectors with an AB loop mutation and those with an FG loop mutation. The present study shows that mutation of the AB loop in the fiber knob is better than deletion of the FG loop for lowering transgene expression, at least with the triple-mutant Ad vector. Cells transduced with Ad/ΔF(AB)ΔP-S35-L2 or Ad/ΔF(FG)ΔP-S35-L2 produced luciferase at rates of only 0.003 and 0.42%, respectively, relative to the rate of luciferase production in cells transduced with Ad-L2 (Fig. 2A). The FG loop mutation in the fiber knob might continue to facilitate a weak interaction between CAR and the fiber knob. One of the interesting findings is that the amounts of Ad/ΔF(AB)ΔP-S35-L2 DNA and Ad/ΔF(FG)ΔP-S35-L2 DNA in the cells were only 10-fold lower than those of Ad-L2 DNA, even after the cells were treated with trypsin–EDTA and DNase I (Fig. 2B). Therefore, the cells would take up considerable amounts of Ad/ΔF(AB)ΔP-S35-L2 and Ad/ΔF(FG)ΔP-S35-L2 nonspecifically, although neither vector mediated luciferase production.

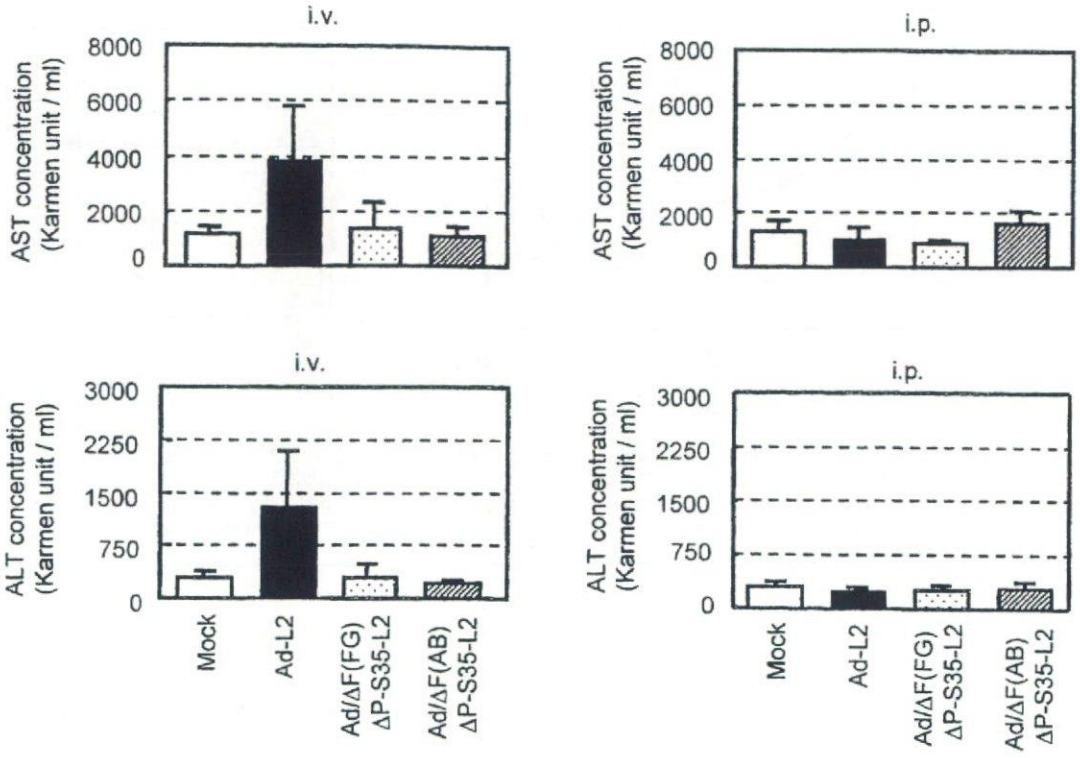

FIG. 7. Serum enzymes levels after systemic administration of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 into mice. Blood samples were collected from the inferior vena cava 48 hr after intravenous (3.0×10^{11} VP) or intraperitoneal (1.0×10^{11} VP) injection of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2. Serum samples were collected into separate tubes containing no anticoagulant for coagulation, and aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels in serum were measured with a Transaminase-CII kit. All data represent the means ± SD of four mice.

We demonstrated that the newer triple-mutant Ad vector containing a mutation of the AB loop mediates approximately 15,000- and 500-fold lower mouse liver transduction by intravenous and intraperitoneal injection, respectively, than the conventional Ad vector (Fig. 3). However, the amounts of triple-mutant Ad vector DNA in the liver after intravenous or intraperitoneal injection were similar to or higher than those with the conventional Ad vector (Fig. 4). The difference between luciferase production and Ad DNA accumulation in the liver would be due to higher accumulation of triple-mutant Ad vector DNA in the NPCs (Kupffer cells and endothelial cells) (Fig. 5) as well as to nonspecific viral uptake in the liver. Because higher amounts of the triple-mutant Ad vector were taken up nonspecifically into the cultured cells (Fig. 2B), the liver cells *in vivo* would also take up large amounts of virus nonspecifically. Our previous report showed that most Ad DNA (especially the triple-mutant Ad DNA) taken up in NPCs disappears 48 hr after intravenous administration (Koizumi *et al.*, 2003a). Triple-mutant Ad vectors in NPCs might be resolved, resulting in significantly lower gene expression in the liver. Furthermore, Miyazawa *et al.* have reported that exchanging the Ad type 5 fiber (subgroup C) for the Ad type 7 fiber (subgroup B) on an Ad type 5 capsid resulted in altered cellular trafficking compared with parental Ad type 5 (Miyazawa *et al.*, 1999, 2001). Therefore, even if the triple-mutant Ad vector, in which the Ad type 5 fiber shaft was exchanged for the Ad type 35 fiber shaft (subgroup B), was taken up into cells, it might have defects in viral escape from the endosome to the cytoplasm (Nicklin *et al.*, 2005).

We and others have reported that the conventional Ad vector has a half-life in the bloodstream of approximately 2 min after intravenous injection (Alemany *et al.*, 2000; Alemany and Curiel, 2001; Koizumi *et al.*, 2003a; Sakurai *et al.*, 2003). The triple-mutant Ad vector and the conventional Ad vector presented similar clearance kinetics from the circulation after intravenous injection (Fig. 6A). In the case of intraperitoneal injection, the $AUC_{2\text{-}180}$ value of the triple-mutant Ad vector in the bloodstream was approximately five to seven times higher than that of the conventional Ad vector (Fig. 6B). It remains unclear why intraperitoneally injected vectors persist longer in the blood (Akiyama *et al.*, 2004). The vector might associate with blood factors or cells (Shayakhmetov *et al.*, 2005). It was also found that intraperitoneally injected vectors accumulated more in NPCs than in PCs (Fig. 5B). This NPC-mediated uptake might be an obstacle for the targeted Ad vector when it is intraperitoneally injected. Because the present vector has no targeted ligands, more detailed studies should be done after high-affinity ligands are displayed on the vectors. If high levels of NPC-mediated uptake were avoided by the addition of ligands,

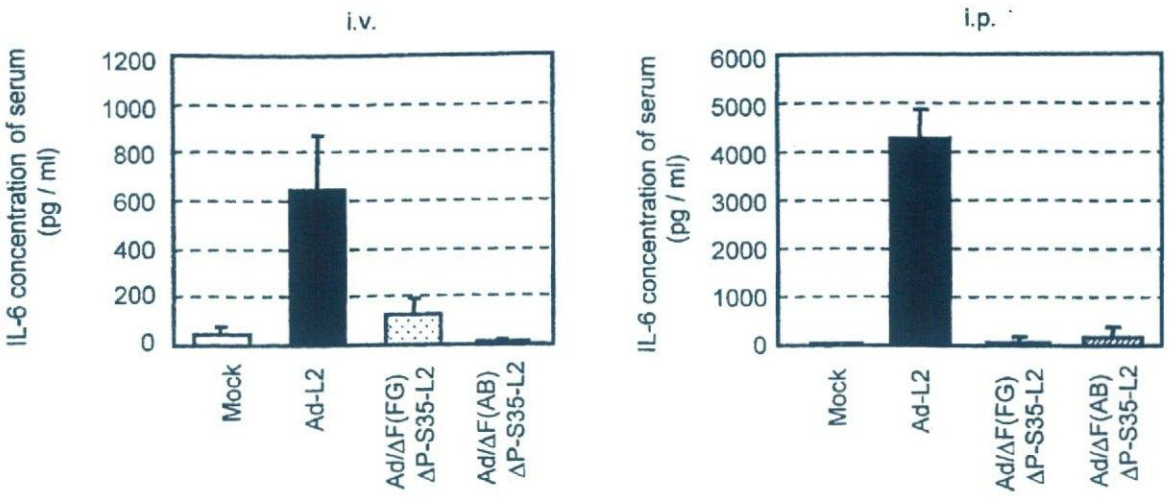

FIG. 8. Interleukin (IL)-6 levels in serum after systemic administration of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2 into mice. Blood samples were collected from the inferior vena cava 3 hr after intravenous (3.0×10^{11} VP) or intraperitoneal (1.0×10^{11} VP) injection of Ad-L2, Ad/ΔF(FG)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-L2. Serum samples were collected into separate tubes containing no anticoagulant for coagulation, and IL-6 levels in the serum were measured by ELISA. All data represent the means ± SD of six mice.

the increased persistence of the vector in the blood in the case of intraperitoneal injection might give us a way to overcome obstacles to the development of targeted Ad vectors.

In the *in vivo* viral uptake experiment, the yield of viral DNA from total liver (Fig. 4) was an order of magnitude more than the total yield obtained from PCs and NPCs (Fig. 5). We speculated that extracellular virus, which would be present in the yield obtained from total liver but not in the yield obtained from fractionated cells, might be involved, because extracellular virus would be moved by collagenase treatment into the fractionated cells. To demonstrate this, we examined the effect of collagenase or trypsin treatment on the amounts of viral DNA in cultured cells. SK HEP-1 cells were transduced with Ad-L2 or Ad/ΔF(AB)ΔP-S35-L2 (3000 VP/cell). After a 3-hr culture period, the cells were washed with PBS, collagenase (0.01%), or trypsin (0.025%). The amounts of Ad genomic DNA in cells were

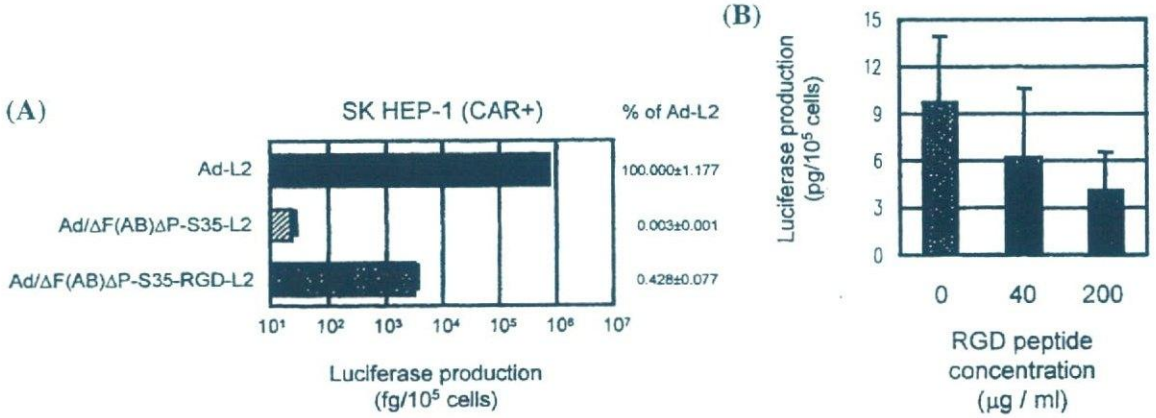

FIG. 9. Luciferase production in human cells transduced with Ad vectors containing RGD motif in the fiber knob. (**A**) Comparison of luciferase production in human cells transduced with Ad-L2, Ad/ΔF(AB)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-RGD-L2. SK HEP-1 cells were transduced with 3000 VP/cell of Ad-L2, Ad/ΔF(AB)ΔP-S35-L2, or Ad/ΔF(AB)ΔP-S35-RGD-L2 for 1.5 hr. After culture for 48 hr, luciferase production in the cells was measured by a luciferase assay system. The data are expressed as means ± SD ($n = 4$). The relative expression levels are described by designating the value of Ad-L2 as 100. (**B**) Effects of RGD peptide on the transduction efficiency of Ad/ΔF(AB)ΔP-S35-RGD-L2 into SK HEP-1 cells. SK HEP-1 cells were preincubated with RGD peptide (0, 1.6, 8, or 40 μg/ml) for 10 min. The cells were then transduced with 300 VP/cell of Ad/ΔF(AB)ΔP-S35-RGD-L2 for 0.5 hr in the presence of RGD peptide. After culture for 48 hr, luciferase production was measured by a luciferase assay system. The data are expressed as means ± SD ($n = 6$).

quantified with the TaqMan fluorogenic detection system. Data showed that collagenase or trypsin treatment decreased 2- to 3.5-fold the amounts of Ad DNA in cells (data not shown), suggesting that nonspecific viral association would lead to the overestimation of viral uptake by the cells. Therefore, the difference in the yields between Figs. 4 and 5 would be reasonable.

The initiation of inflammation and strong innate immunity responses occur after systemic administration of Ad vectors to animals and humans, and this toxicity limits the utility of Ad vectors for gene therapy (Muruve, 2004). Increased cytokine production after injection of Ad vectors was reported to be due to the introduction of input Ad vectors to Kupffer cells in the liver and dendritic cells (Lieber *et al.*, 1997; Schnell *et al.*, 2001, Morral *et al.*, 2002; Reid *et al.*, 2002; Philpott *et al.*, 2004). Lieber *et al.* have reported that IL-6 production in mice after injection of Ad vectors was decreased by preinjection of $GaCl_2$, which can decrease the levels of Kupffer cells in mouse liver (Lieber *et al.*, 1997). On the other hand, Muruve reported that Kupffer cells avidly take up systemically administered Ad vectors, but the blockade of Kupffer cells has minimal impact on the innate immune response in the liver (Muruve, 2004). Although our experiment showed that large amounts of the triple-mutant Ad vector accumulated in the NPC fraction, which contains Kupffer cells and liver sinusoidal (endothelial) cells, IL-6 was not produced in mice after injection of the triple-mutant Ad vector (Fig. 8). Therefore, Ad vectors would be capable of inducing IL-6 production in cells other than Kupffer cells. De Geest *et al.* reported that the spleen, not the liver, is the major site of IL-6 production after Ad vector transfer (De Geest *et al.* 2005), although in the present study the triple-mutant Ad vector accumulated in the spleen as much as did the conventional Ad vector (Fig. 4). There are several possible reasons why the triple-mutant Ad vector does not mediate IL-6 production *in vivo*. Philpott *et al.* have reported that maturation of dendritic cells, which are IL-6-producing cells, by infection with Ad vectors requires the RGD motif of the Ad penton base (Philpott *et al.*, 2004). The triple-mutant Ad vector without the RGD motif in the penton base would interact differently with IL-6-producing cells than would the conventional Ad vector. Liu *et al.* have reported that conventional Ad vectors are delivered into liver sinusoid cells as well as Kupffer cells after systemic injection (Liu *et al.*, 2003). Schiedner *et al.* have reported that Ad vectors activate liver endothelial cells after infection of Kupffer cells (Schiedner *et al.*, 2003). The difference in distribution between the triple-mutant Ad vector and the conventional Ad vector in liver sinusoid and Kupffer cells may contribute to IL-6 production. Furthermore, Zsengeller *et al.* demonstrated that Ad vector internalization and endosomal escape were required for cytokine induction in alveolar macrophages (Zsengeller *et al.*, 2000). The triple-mutant Ad vector might have reduced the level of endosomal escape in comparison with the conventional Ad vector. Specific viral component(s) of the Ad vector, viral distribution in the specific cell types, and/or viral distribution in the cellular compartment might determine IL-6 production. Elucidation of a mechanism for innate immune responses after administration of Ad vectors might be obtained by investigating the precise distribution of the triple-mutant Ad vector after systemic administration.

Finally, regarding the feasibility of using triple-mutant Ad vectors as targeted vectors, we constructed triple-mutant Ad vectors containing the RGD motif, which has high affinity for α_v integrins, in the HI loop of the fiber knob. This triple-mutant Ad vector with the RGD motif was found to show efficient *in vitro* gene transfer through RGD peptides in the fiber knob (Fig. 9). We also examined *in vivo* luciferase production and serum levels of AST, ALT, and IL-6 in mice after administration of this RGD motif-containing vector. However, the patterns of luciferase production *in vivo* (Fig. 3) and the serum levels of AST, ALT, and IL-6 (data not shown) postadministration were similar to those produced with the triple-mutant Ad vector without any ligands. Because the RGD peptide used in the present study was first isolated from a phage display library and used to "home" to endothelial cells in tumor tissue (Koivunen *et al.*, 1995; Pasqualini *et al.*, 1997), and because the endothelial cells in normal tissue do not express higher levels of α_v integrin than are found in tumor tissue, the RGD motif may not be the optimal peptide for increasing *in vivo* transduction efficiency after systemic injection. Another possible reason why this RGD motif-containing vector did not increase transduction *in vivo* is that the affinity of the introduced RGD peptides for integrin might be weak compared with the knob–CAR interaction. Furthermore, fiber mutation might affect encapsidation, stability, and flexibility of the vector. The resultant subtle alteration in fiber biology might negatively affect the transduction efficiency of this vector. Altered fiber biology might also be involved in the lower gene transduction efficiency of the triple-mutant Ad vector.

For the development of targeted Ad vectors, incorporation of a foreign ligand (i.e., peptide), one with high affinity for a specific cellular receptor, into the capsids of Ad vectors will also be required. The triple-mutant Ad vector was designed to have unique restriction sites (*Csp*45I or *Cla*I) in both the HI loop and the C-terminal coding region of the fiber knob (Mizuguchi *et al.*, 2001; Koizumi *et al.*, 2001, 2003b). Therefore, any targeting ligand can be easily displayed in the fiber knob of the triple-mutant Ad vector by cloning its gene into either of these regions, using simple *in vitro* ligation.

In summary, we have further improved the triple-mutant Ad vector by ablating CAR, α_v integrin, and HSG binding by introducing a mutation of the AB loop into the fiber knob (R412S, A415G, E416G, and K417G). This vector was found to mediate significantly lower tissue transduction both *in vitro* and *in vivo* (intravenous and intraperitoneal injection). Furthermore, we showed that this triple-mutant Ad vector reduces (or blunts) liver toxicity and innate immunity responses (IL-6 production). Inclusion of the RGD peptide in the HI loop of the fiber knob of the triple-mutant Ad vector restored gene transfer activity. Thus, the newer triple-mutant Ad vector will likely be a fundamental vector for targeted gene delivery.

Received October 25, 2005

Abstract: Stem cells, including embryonic stem (ES) cells, mesenchymal stem cells (MSCs), and hematopoietic stem cells (HSCs), are defined by their capacity for self-renewal and multilineage differentiation. Efficient gene transfer into stem cells is essential for the basic research in developmental biology and for therapeutic applications in gene-modified regenerative medicine. Adenovirus (Ad) vectors, based on Ad type 5, can efficiently and transiently introduce the exogenous gene into many cell types via the primary receptor, coxsackievirus, and adenovirus receptor (CAR). However, some kinds of stem cells, such as MSCs and HSCs, cannot be efficiently transduced with conventional Ad vectors based on Ad serotype 5 (Ad5), because of the lack of CAR expression. To overcome this problem, fiber-modified Ad vectors and an Ad vector based on another serotype of Ad have been developed. Here, we review the advances in the development of Ad vectors suitable for stem cells and discuss their application in basic biology and clinical medicine.

Keywords: Adenovirus; stem cell; gene therapy; regenerative medicine; review

Introduction

Adenovirus (Ad) is a nonenveloped virus containing an icosahedral protein capsid with a diameter of approximately 80 nm. At least 51 serotypes of human Ad have been identified and classified into six different subgroups (A−F), many of which are associated with respiratory, gastrointestinal, or ocular diseases. Of them, Ad serotype 5 (Ad5) and Ad serotype 2, both belonging to subgroup C, have been the most extensively studied for use as vectors in gene therapy applications. Ad capsids consist of three major protein components: the hexon, the penton base, and the fiber. Hexon proteins comprise each geometrical face of the capsid, while penton bases associate with fiber proteins to form penton capsomer complexes at each of the 12 vertices (Figure 1A). The two components of the penton capsomer, the fiber and penton base, interact with distinct cell surface receptors during the entry of Ad into susceptible cells. Fiber proteins consist of three distinct domains: the tail, the shaft, and the knob. Each domain has distinct functions in host cell infection. The amino-terminal tail anchors the fiber to the Ad capsid through association with the penton base.[1] The shaft extends away from the virion surface and, in Ad5, is composed of 22 pseudorepeats of 15 amino acids in a triple-β-spiral conformation.[2] By extending the knob away from the virion, the shaft facilitates its interaction with the host

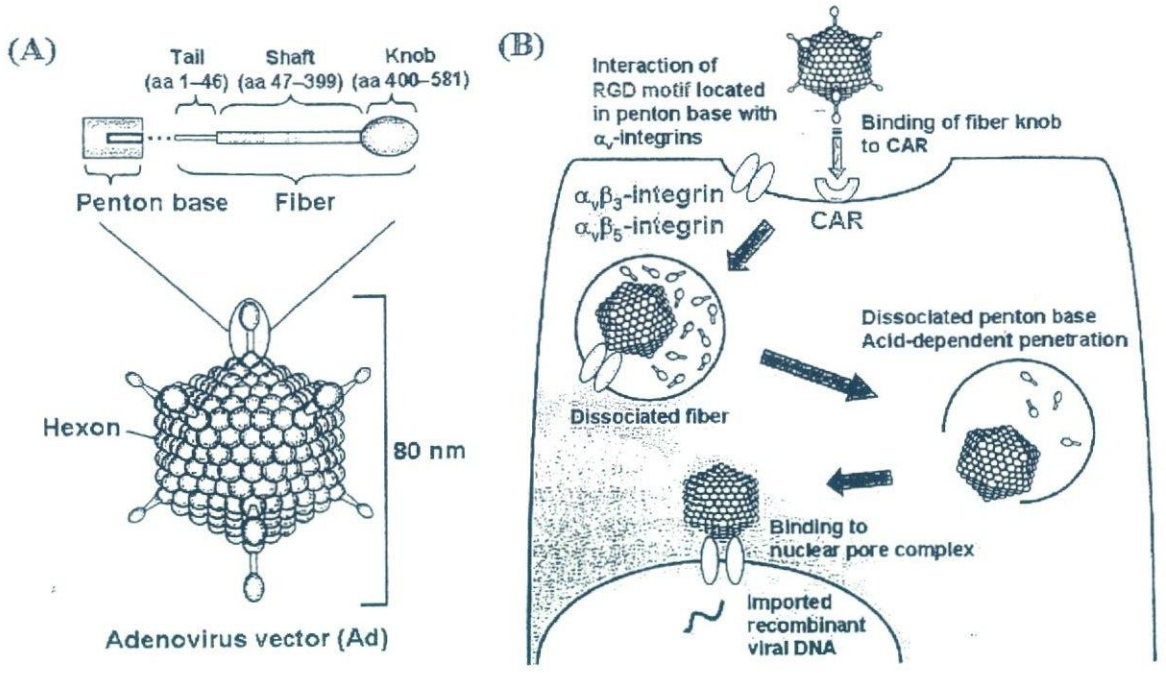

Figure 1. Structure and gene transduction pathway of the Ad vector. (A) The double-stranded virus genome is packaged within an icosahedral protein capsid. Hexon proteins comprise each geometrical face of the capsid, while penton bases associate with fiber proteins to form penton capsomer complexes at each of the 12 vertices. The fiber is composed of the tail, shaft, and knob domain. (B) The Ad vector binds to CAR following internalization in the cells and releases the viral DNA into the nuclei.

receptor.[1] The trimeric subunits of the carboxyl C-terminal knob domain are responsible for binding to the host's primary cellular receptor.[3,4]

Human Ad5 contains a linear, approximately 36 kb, double-stranded DNA genome encoding more than 70 gene products. The viral genome contains five early transcription units (E1A, E1B, E2, E3, and E4), two early delayed (intermediate) transcription units (pIX and IVa2), and five late units (L1–L5), which mostly encode structural proteins for the capsid and internal core. Inverted terminal repeats (ITRs) at the end of the viral genome function as replication origins. The E1A gene is the first transcription unit to be activated shortly after infection and is essential to the activation of other promoters and the replication of the viral genome. In the first-generation Ad vectors, the E1 (E1A and E1B) gene is deleted and the virus propagated in E1-transcomplementing cell lines, such as 293,[5] 911,[6] or PER.C6 cells.[7] The E3 region-encoded proteins modulate the host defense but are not required for viral replication in vitro; thus, the E3 region is often deleted to enlarge the packagable size limit for foreign genes. Since up to 3.2 and 3.1 kb of the E1 and E3 regions, respectively, can be deleted[8] and approximately 105% of the wild-type genome can be packaged into the virus without affecting the viral growth rate and titer,[9] E1/E3-deleted Ad vectors allow the packaging of approximately 8.1–8.2 kb of foreign genes.[8]

The coxsackievirus and adenovirus receptor (CAR), which is a broadly distributed type I membrane protein, has been identified as the primary receptor for Ad of subgroups A and C–F.[10–12] The entry of Ad5 into cells is initiated by the

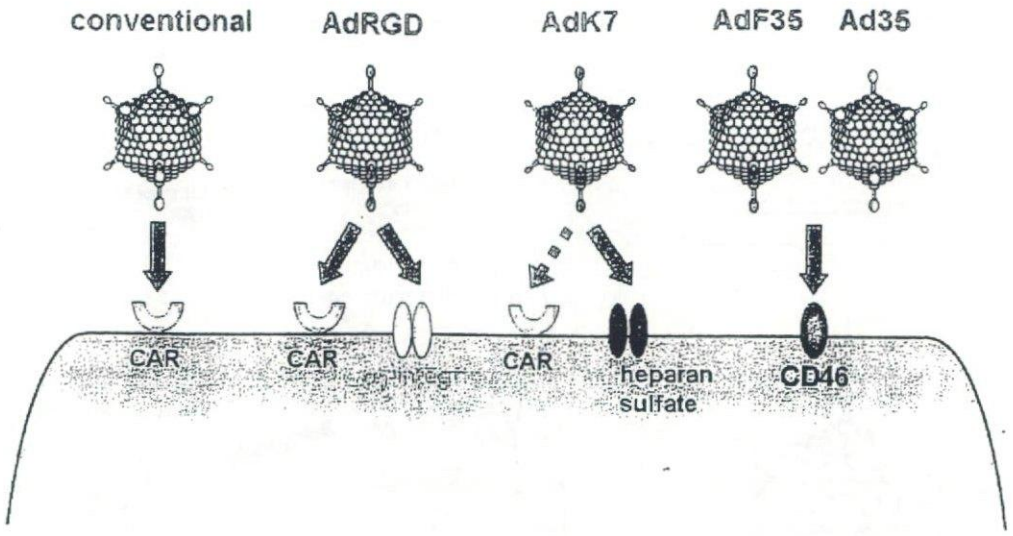

Figure 2. Characteristics of gene delivery by various types of Ad vectors. The conventional Ad vector infects via CAR. The AdRGD vector contains a RGD peptide motif in the HI loop of the fiber knob and infects via αv integrin as well as CAR. The AdK7 vector contains a polylysine peptide in the C-terminus of the fiber knob and infects via heparan sulfate as well as CAR. It is uncertain whether the AdK7 vector infects via CAR. The Ad35 and AdF35 vectors, which contain a fiber protein derived from the Ad5 fiber tail and the Ad35 fiber knob and shaft, infect via CD46.

attachment of fiber on the surface of the capsid to the CAR on the cell surface (Figure 2). The affinity of the RGD (Arg-Gly-Asp) peptide at the penton base of the Ad5 capsid for the cell surface molecules of the integrin family, such as $\alpha_v\beta_5$, $\alpha_v\beta_3$, $\alpha_5\beta_1$, and $\alpha_v\beta_1$, aids in the internalization of Ad5 into the cell.[13−15] Furthermore, heparan sulfate glycosaminoglycans have also been reported to serve as primary attachment sites for Ad2 and Ad5.[16] The abundant expression of these receptors in various cells determines the wide tropism of Ad vectors. Internalized Ad reaches the endosomal pathway and avoids lysosomal degradation (Figure 1B). Inside the endosome, a stepwise disassembly program takes place, allowing the Ad to release its genome into the nucleus. During this process, the pH of the endosome decreases, leading to the release of the fiber from the virion and the dissociation of the penton base.[17] The resulting endosome rupture allows viral DNA to escape from inside the degraded capsid and to enter the nucleus (Figure 1B). During this process, the terminal protein plays a crucial role in translocating the Ad genome into the nucleus. This uncoating process of the Ad starts immediately after internalization and ends 40 min after infection with the translocation of the Ad into the nucleus. As early as 60 min after infection, the Ad begins to transcribe its genome in the host cell.[18]

Although Ad vectors mediate extremely high transduction efficiency, gene transfer with Ad vectors is less efficient in some kinds of cells, such as mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs), dendritic cells, T cells, smooth muscle cells, skeletal muscle cells, and others because of the scarcity of CAR on their cell surfaces. Modification of the Ad fiber proteins has been used to successfully overcome this obstacle.[19,20] One is constructed by the addition of foreign peptides to the HI loop or C-terminus of the fiber knob of an Ad vector.[21−25] Enhanced gene transfer has been

reported, on the basis of the use of mutant fiber proteins containing either an RGD peptide (AdRGD vector)[21-26] or a stretch of lysine residues [K7 (KKKKKKK) peptide] (AdK7 vector),[21,25,26] which target αv integrins or heparin sulfates on the cell surface, respectively (Figure 2). Altered vector tropism was reported with the substitution of the Ad5 fiber protein with that of Ad belonging to subgroup B, such as Ad types 3, 11, and 35.[27-31] These fiber-modified Ad vectors infect cells via CD46, CD80, and CD86, which have recently been identified as the cellular receptors of Ad belonging to subgroup B (Figure 2).[32-36] Mercier et al. described the creation of a chimeric Ad vector encoding the reovirus attachment protein σ1, which targets cells expressing junctional adhesion molecule 1.[37]

Several groups have developed an Ad vector from the entire Ad type 35 (Ad35) or Ad type 11 (Ad11) and have demonstrated that the Ad35 and Ad11 vectors exhibit higher transduction efficiencies into hematopoietic progenitor and dendritic cells compared with the conventional Ad5 vector (Figure 2).[38-43] As other approaches to changing the vector tropism, modification of the Ad vector with the antibodies, the fusion protein composed of CAR and the cell binding domain, cationic lipid, or macromolecules has been reported.[19,20] Here, we highlight the genetic manipulations of stem cells by the Ad vector and fiber-modified Ad vector for basic research and therapeutic usage. Recent advances in Ad vector-mediated gene transfer into stem cells, such as embryonic stem (ES) cells, mesenchymal stem cells (MSCs), and hematopoietic stem cells (HSCs), will be discussed.

Gene Transfer into Stem Cells

Stem cells are defined as cells which possess the abilities of self-renewal and multilineage differentiation. Stem cells have been isolated from a wide variety of tissues, and in general, their differentiation potential may reflect the local environment. They lack tissue-specific characteristics but under the influence of appropriate signals can differentiate into specialized cells with a phenotype distinct from that of their precursor. Gene therapy applications that target stem

cells offer great potential for the treatment of many kinds of diseases. Despite this promise, clinical success has been limited by poor rates of gene transfer and poor levels of gene expression. Therefore, an efficient gene delivery system needs to be developed for stem cell gene therapy.

Gene Transfer into Embryonic Stem Cells. ES cells are pluripotent cell lines derived from the inner cell mass of the developing blastocyst.[44−46] With the establishment of human ES (hES) cells, they have been used as a renewable source of transplantable tissue-specific stem cells.[47−49] ES cells differentiate spontaneously in vitro in a random manner into a mixture of differentiated cells. The protocols for the differentiation of ES cells enriched for a specific lineage have been developed in both the mouse ES (mES)[50,51] cell and hES cell systems,[52,53] although the differentiated cells are still relatively heterogeneous. Therefore, further research is needed to allow controlled directed differentiation of ES cells into pure cultures of committed cells. One of the most powerful techniques for controlled differentiation is genetic manipulation. Electroporation methods,[54] retroviral vectors,[55,56] lentiviral vectors,[57−59] and a supertransfection method based on a replication system using the polyoma replication origin and large T antigen[60] have been used for exogenous gene expression in ES cells, although lentiviral vectors have been shown to be ineffective at expressing exogenous genes in mES cells, but not in hES cells.[57,59] In plasmid-based systems such as eletroporation and supertransfection methods, stable cell lines are generated by selection using a drug resistance gene. All these methods mediate long-term constitutive gene expression, although a long-term gene expression system such as that as described above may be problematic for use in therapeutic applications, because the gene is continuously expressed even after cell differentiation. There is thus a need for efficient vector systems for transient expression.

The Ad vector has been thought to be inappropriate for gene transfer into ES cells.[61] It has been reported that the retrovirus vector preferentially transduced ES cells, while the Ad vector containing the cytomegalovirus (CMV) promoter preferentially transduced embryonic fibroblasts as feeders in the ES culture.[61] However, it was found that the

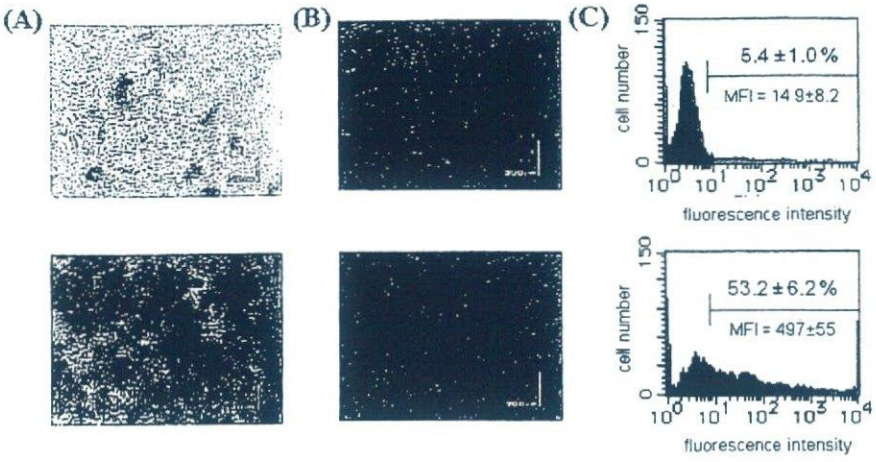

Figure 3. Improved transduction efficiency in the stem cells by the optimized Ad vectors. (A) mES cells were transduced with the LacZ-expressing conventional Ad5 vector containing the CMV promoter (top) or EF-1α promoter (bottom). (B) hMSCs were transduced with the LacZ-expressing Ad5 vector (top) or AdK7 vector (bottom). Both vectors have the CA promoter. (C) Human CD34+ cells were transduced with the GFP-expressing Ad5 vector (top) or Ad35 vector (bottom). Both vectors have the CMV promoter. MFI is the mean fluorescence intensity.

choice of a promoter is important for the efficient expression of exogenous genes in mES cells (Figure 3A). In the transient expression system using a cationic liposome−plasmid complex, the EF-1α (elongation factor 1α) and CA promoter (β-actin promoter/CMV enhancer) were shown to be highly active in mES cells while the CMV promoter was inactive.[62] More recently, we reported that the Ad vector containing the EF-1α or CA promoter has mediated the efficient expression of the reporter gene in mES cells, whereas the Ad vector containing the Rous sarcoma virus (RSV) or the CMV promoter has exhibited little expression.[63] Because CAR was highly expressed in mES cells but not in feeder cells,[63] the Ad vector could be a powerful tool for the genetic manipulation of mES cells when an appropriate promoter is used. To date, although we have no idea about the expression of CAR in hES cells, the Ad vector was reported to mediate the reporter gene expression in both mES cells and hES cells,[64] suggesting that hES cells may also express CAR on their cell surfaces.

As a result of the comparative analysis of mES cells transduced with various types of fiber-modified Ad vectors, the conventional Ad vector exhibited highly efficient and specific transduction, whereas the AdRGD and AdK7 vectors transduced mES cells and feeder cells (embryonic fibroblasts) to the same degree.[63] Therefore, the conventional Ad vector containing the EF-1α or CA promoter should be appropriate when only ES cells are transduced. In turn, the AdRGD or AdK7 vector is adequate when both ES cells and feeder cells are transduced.

The conventional Ad vector containing the EF-1α promoter was applied for the transduction of functional genes. It is well-known that the activation of signal transducer and activator of transcription 3 (STAT3) is essential for leukemia inhibitory factor (LIF)-mediated mES cell self-renewal, and the inhibition of LIF/STAT3 signaling leads to either apoptosis or differentiation.[65] It is also known that transcription factor Nanog maintains the pluripotency of mES cells in a manner that is independent of LIF/STAT3 signaling.[66,67] Ad vector-mediated STAT3F (STAT3 dominant-negative mutant) transduction strongly promoted mES cells to cell differentiation into three germ layers without any nonspecific toxicity.[63] The co-infection of the STAT3F-expressing Ad vector and the Nanog-expressing Ad vector showed that the differentiation suppressing ability of Nanog negated the differentiation promoting function of STAT3F and that mES cells maintained their undifferentiated state.[63] Thus, the differentiation of ES cells could be controlled by the transduction of differentiation-key regulator genes with the Ad vector. ES cells might differentiate into hematopoietic progenitor, pancreatic β cells, or neurons by the Ad vector-mediated introduction of HoxB4,[68,69] Pax4,[70] or nuclear receptor-related I,[71] respectively.

marrow, were first identified as bone-forming progenitor cells from rat marrow.[72] MSCs represent a very small fraction, 0.001−0.01% of the total population of nucleated cells in marrow.[73] They have the capacity to differentiate into cells of connective tissue lineages, including bone, fat, cartilage, and muscle. Recently, it has been reported that MSCs can differentiate into other lineages, such as neurons,[74] hepatocytes,[75] and insulin-producing cells.[76] Therefore, MSCs have attracted a great deal of interest because of their potential use in regenerative medicine and tissue engineering. To date, MSCs could be differentiated in vitro into proper lineages via a change in the culture conditions.[77] Another method for the in vitro differentiation is to genetically modify MSCs.[78,79] Although exogenous gene transfer into human MSCs (hMSCs) has been reported by using a conventional Ad vector, its transduction efficiency is quite low due to the scarcity of CAR.[80,81] Therefore, hMSCs have been transduced with high titers (more than 1000 infectious units/cell) of Ad vectors.[80,81] Fiber-modified Ad vectors have been applied for hMSCs to improve the transduction efficiency.[79,82,83] hMSCs infected with the AdRGD vector containing the BMP2 gene produced larger amounts of BMP2 than cells infected with the conventional Ad vector and efficiently differentiated into the osteogenic lineage.[82,83] Highly efficient transduction of hMSCs was achieved with tropism-modified Ad5 vectors carrying fiber shaft domains and knobs of different serotypes of Ad, such as Ad16, Ad35, or Ad50.[84] In a systematic comparison with various types of fiber-modified Ad vectors, the AdK7 vector is the most efficient for hMSCs and exhibited a 460-fold higher transduction efficiency than the conventional Ad vector.[79] The AdRGD vector or the Ad vector containing the Ad35 fiber (AdF35) exhibits a 16 or 130 times higher transduction efficiency, respectively, than the conventional Ad vector.[79] hMSCs are found to express CD46, which is the primary receptor for Ad35, but not CAR.[79] In conclusion, the AdK7 or AdF35 vector is the most appropriate for the transduction of hMSCs (Figure 3B).

Gene Transfer into Hematopoietic Stem Cells. Hematopoietic stem cells (HSCs) are capable of self-renewal and multilineage differentiation into all mature blood cells.[85] HSCs comprise only 0.01% of the whole bone marrow, the tissue in which they primarily reside.[86] Efficient transduction into HSCs would afford the opportunity to treat a number of hematopoietic disorders and would be a powerful tool for

the study of the proliferation, differentiation, and trafficking of HSCs. Although the retroviral and lentiviral transduction of HSCs to achieve stable gene expression has been established,[87,88] stable expression is not always desirable. For example, stable expression of MDR1 gene results in HSC expansion but can cause leukemia upon transplantation to recipient mice.[89] As the Ad vector mediates the exogenous gene expression transiently, this vehicle can be safe for gene therapy. However, the application of conventional Ad vectors for the transduction into human CD34+ cells, which contain a population of HSCs, has been limited because CAR is not expressed at sufficient levels in human CD34+ cells.[90,91] It has been shown that Ad serotype 35 (Ad35), which belongs to subgroup B, is efficient at binding to human CD34+ cells and hematopoietic cell lines.[90,92] We showed that the Ad35 vector, which is composed from the whole Ad35, achieved higher levels of transduction efficiency in human bone marrow CD34+ cells than both conventional Ad5 vectors and AdF35 vectors.[39,93] The expression level of reporter genes in the CD34+ cells transduced with the Ad35 vector was 12−76 and 1.4−3 times higher than that in the cells transduced with the Ad5 and AdF35 vectors, respectively.[39] The transduction efficiency of the Ad35 vector was slightly higher than that of the AdF35 vector, although the reason remains unknown. CD46 is ubiquitously expressed in almost all human cells, including human cord blood CD34+ cells.[94] Therefore, human CD34+ cells would be considered to be a suitable target for the Ad35 vector (Figure 3C). As a result of the systematic comparison of promoters with Ad35 vectors, significantly higher transduction efficiencies were achieved with the EF-1α, CA, and CMV promoter/enhancer with the largest intron of CMV (intron A) (CMVi) promoters. In particular, the CA promoter was found to allow for the highest transduction efficiencies in both the whole human CD34+ cells and the immature subsets.[93] In mice, a population of mouse bone marrow highly enriched for HSC, called side population (SP) cells, has been reported to be transduced with the conventional Ad5 vector.[95] This suggests that pure mouse HSCs might express CAR on the cell surface. Further studies are needed to clarify this. The Ad vector-mediated transduction of hematopoietic regulator genes, such as HoxB4,[68,69] Bmi-1,[96] or SCL/Tal-1,[97] into HSCs may be effective for therapeutic use such as HSC expansion, although the Ad vector expressing HoxB4 was unsuccessful because of unexpected HSC differentiation due to its high transduction efficiency.[98]

Conclusions

We have reviewed recent advances in the development of improved Ad vectors for stem cells. Ad vectors have advantages over other viral vectors: the high transduction efficiency, the ease of vector preparation, and the transient expression ability. By the Ad vector-mediated introduction of a differentiation master regulator gene, we could control the differentiation of stem cells. These technical advances should greatly facilitate the analysis of gene function in the stem cells as well as the therapeutic applications of gene-modified stem cells.

Abbreviations Used

ES, embryonic stem; mES, mouse ES; MSCs, mesenchymal stem cells; HSCs, hematopoietic stem cells; Ad, adenovirus; CAR, coxsackievirus and adenovirus receptor; Ad5, Ad serotype 5; ITR, inverted terminal repeats; Ad35, Ad serotype 35; AdRGD vector, Ad vector containing the RGD
