deprivation+cirazoline, 251±5% $P<0.01$; staurosporine+phenylephrine, 614±9% $P<0.01$; staurosporine+cirazoline, 654±16% $P<0.01$; and tunicamycin+phenylephrine, 594±13% $P<0.05$; tunicamycin+cirazoline, 597±10% $P<0.05$) (Fig. 4). Under the three stress conditions, the differences in the efficacies of phenylephrine and cirazoline on LDH release did not differ greatly. However, both agonists were most effective against N2 deprivation stress, where phenylephrine and cirazoline reduced LDH release 34% and 31%, respectively, as compared with the unstressed control (Fig. 4A). These data suggest that α_1-adrenoceptor agonists protected NPC death under several different stress conditions but exhibited different efficacies depending on the particular stress.

3.5. α_1-adrenoceptor agonists do not modulate the proportion of nestin-positive NPCs under stress conditions

Phenylephrine did not affect differentiation of NPCs in cultures with or without bFGF (Fig. 1), and the high proportion (over 98%) of nestin-positive cells remained for ~24 h even in 1 ng/ml bFGF (data not shown). The ability of the agonists to prevent cell death in 1 ng/ml bFGF was thus a direct effect on the nestin-positive NPCs and not an artifact due to contaminating cells. We also examined the effects of stress induced by N2 deprivation, 50 nM staurosporine or 30 ng/ml tunicamycin on NPC differentiation to exclude the possibility that the increased cell numbers observed following α_1-adrenoceptor agonist exposure, as measured by ATP production, were derived from the differentiated cells induced by the stresses. The proportion of nestin-positive NPCs was not changed by N2 deprivation, staurosporine-or tunicamycin-induced stress, and treatment of NPCs with phenylephrine or cirazoline under these stress conditions did not decrease the proportions of nestin-positive cells (Fig. 5).

3.6. Phenylephrine inhibits caspase-3/7-independent cell death

Of the three stress conditions tested, α_1-adrenoceptor agonists most effectively suppressed stress caused by N2 deprivation, as measured by LDH release (Figs. 3 and 4). Whereas cell death induced by bFGF deprivation, staurosporine treatment or tunicamycin treatment probably was caused by activation of various death signaling pathways, the stress caused by N2 deprivation mainly induced caspase-3/7-dependent cell death in NPC cultures (Fig. 6). To ascertain whether α_1-adrenoceptor agonists protect against caspase-3/7-dependent cell death, we examined the effects of α_1-adrenoceptor agonists on cellular caspase-3/7 activities. Stress caused by N2 deprivation induced elevated cellular caspase-3 and caspase-7 activities as compared with non-stress conditions (>2 fold; Fig. 6A). However, the elevated activities of caspases were not changed by treatment of NPCs with phenylephrine (Fig. 6A). Despite a lack of modulation of the cellular caspase activity, phenylephrine suppressed propidium iodide penetration into NPC cytoplasm (45.4%; $P<0.05$, as compared with untreated cells deprived of N2) (Fig. 6B and C). These data indicate that α_1-adrenoceptor agonists selectively protect against caspase-3/7-independent death of NPCs exposed to stress.

4. Discussion

In this study, we prepared highly purified embryonic NPCs (>99% nestin$^+$ cells) from the E14 mouse cortex and found that the cortical embryonic NPCs highly express α_{1A}- and α_{1B}-adrenoceptor genes but express the α_{1D}-adrenoceptor gene at low levels. Our pharmacological experiments also revealed that α_1-adrenoceptor agonists are protective against NPC death induced by various stresses without any modification of the cell differentiation state of the NPCs. Moreover we demonstrated that α_1-adrenoceptor agonists reduced NPC death caused by the N2 deprivation stress without modulation of intracellular caspase-3/7 activities.

The α_1-adrenoceptor is expressed in the ventricular zone and subventricular zone of the embryonic rat forebrain (Pabbathi et al., 1997). The ventricular zone of the embryonic cerebral cortex contains both undifferentiated NPCs and differentiated nascent neuronal cells. Our quantitative RT-PCR analysis showed that purified cortical NPCs express α_{1A}- and α_{1B}-adrenoceptor genes at high levels compared with the E14 embryonic telencephalon, suggesting that the undifferentiated NPCs highly expressed the α_{1A}- and α_{1B}-adrenoceptor genes. We could not confirm the expression of α_1-adrenoceptor proteins in NPCs because of low specificity of commercially available antibodies against α_1-adrenoceptor in immunocytochemical experiments with NPCs (data not shown). However, we demonstrated that α_1-adrenoceptor agonists have protective effects against cell death in NPCs, indicating the presence of the α_1-adrenoceptors in NPCs.

The chemical structure of phenylephrine ((*R*)-3-[1-hydroxy-2-(methylamino) ethyl] phenol) differs from that of cirazoline (2-[(2-cyclopropylphenoxy) methyl]-4, 5-dihydro-1H-imidazole). However, both α_1-adrenoceptor agonists had the same effect on NPC death induced by a moderate concentration (1 ng/ml) of bFGF, nutritional deprivation (no N2 supplementation), staurosporine treatment or endoplasmic reticulum stress (tunicamycin treatment), indicating that the effects were specifically mediated by α_1-adrenoceptors. It is well known that cell death can be induced via multiple apoptosis signaling pathways that are specifically activated by different stresses. Although the α_1-adrenoceptor agonists were able to protect NPCs from death induced by the stresses we tested, the molecular mechanism that underlies this broad protection is unknown. However, treatment of NPCs with α_1-adrenoceptor agonists failed to decrease the activities of caspase-3 and caspase-7, which are activated in the apoptosis pathway. Instead, α_1-adrenoceptor agonists reduced propidium iodide incorporation induced by stress caused by N2 deprivation. These data suggest that α_1-adrenoceptor agonists protect against necrotic NPC death but not apoptotic NPC death.

Phenylephrine or cirazoline protects against cell death induced by bFGF deprivation as well as by STS and nutritional deprivation, or treatment with staurosporine or tunicamycin. Niidome et al. (Niidome et al., 2006) showed that NPC death resulting from growth factor deprivation is caused by both caspase-dependent and -independent pathways in concert with oxidative stress, suggesting that α_1-adrenoreceptor agonists may also protect against NPC death induced by oxidative stresses. On the other hand, application of phenylephrine is effective only against cell death induced by 1.0 ng/ml bFGF. Complete

deprivation of growth factors activates multiple cell death pathways, including apoptosis, necrosis and the oxidative cell death pathway, in cultured NPCs (Niidome et al., 2006). Therefore, the application of phenylephrine is unlikely to be effective against NPC death induced by the overlapping activation of multiple death pathways after complete loss of growth factor support.

In a recent study, Hiramoto et al. (2006) reported that the stimulation of α_1-adrenoreceptors by phenylephrine or by L-epinephrine induces the proliferation of NPCs derived from cultured neurospheres. Our data indicate that α_1-adrenoreceptor agonists do not induce proliferation of purified NPCs. It is known that the neurospheres have the 3D organization in which nestin-positive (progenitor) cells surround a large core of differentiated GFAP-positive (glial) and β-tubulin III-positive (neuronal) cells (Campos, 2004). As such, the NPC cultures prepared from neurospheres could also contain glial and neuronal cells. Thus, the difference between these data may have resulted from differences in the NPC preparation methods and from the purity of the nestin-positive NPCs.

Transplantation of neural stem and progenitor cells into patients with intractable neurological diseases is considered an effective strategy for neural regeneration therapy reviewed in Lindvall et al., (2004). Studies on cell transplantation/implantation for CNS disorders have indicated that neural stem cells and progenitor cells have the ability to replace lost neurons and to repair the damaged nervous system (Chu et al., 2004). However, a large proportion of grafted cells is lost due to early necrotic death. Thus, the low rate of graft survival reduces the effectiveness of such therapies (Emgard et al., 2003). Here we demonstrated that α_1-adrenoceptor agonists protect against NPC death (probably necrotic death) induced by various stresses. We also demonstrated that α_1-adrenoceptor agonists with this protective effect did not modify the cell differentiation state of the NPCs. Thus, α_1-adrenoceptor agonists may be useful for the preparation and maintenance of neural stem and progenitor cells for transplantation therapy, as they are likely to increase cell viability without induction of unexpected cell differentiation. Moreover, phenylephrine is a popular and safe drug that is used as a non-prescription decongestant (Chua and Benrimoj, 1988) Therefore, phenylephrine may be easily applied as an additional reagent in the cultivation medium of neural stem and progenitor cells for transplantation therapy.

Abstract

Overexpression of ubiquitin C-terminal hydrolase L1 (UCH-L1) in mice rescues amyloid β-protein-induced decreases in synaptic plasticity and memory. However, the physiological role of UCH-L1 in the brain is not fully understood. In the present study, we investigated the role of UCH-L1 in the brain by utilizing gracile axonal dystrophy (*gad*) mice with a spontaneous deletion in the gene *Uch-l1* as a loss-of-function model. Although *gad* mice exhibit motor paresis beginning at ~ 12 weeks of age, it is possible to analyse their brain phenotypes at a younger age when no motor paresis is evident. Maintenance of memory in a passive avoidance test and exploratory behaviour in an open field test were reduced in 6-week-old *gad* mice. The maintenance of theta-burst stimulation-induced long-term potentiation (LTP) of field synaptic responses from Schaffer collaterals to CA1 pyramidal cells in hippocampal slices was also impaired in *gad* mice. The LTP in *gad* mice was insensitive to actinomycin D, suggesting that a transcription-dependent component of the LTP is impaired. Phosphorylation of cyclic AMP response element binding protein (CREB) in the CA1 region of hippocampal slices from *gad* mice occurred earlier than in the slices from wild-type mice and was transient, suggesting that CREB phosphorylation is altered in *gad* mice. These results suggest that memory in passive avoidance learning, exploratory behaviour and hippocampal CA1 LTP are reduced in *gad* mice. We propose that UCH-L1-mediated maintenance of the temporal integrity and persistence of CREB phosphorylation underlies these impairments.

Introduction

Ubiquitin C-terminal hydrolase L1 (UCH-L1) is a deubiquitinating enzyme (Wilkinson *et al.*, 1989) that is exclusively expressed in the brain and testis, and its expression is neuron-specific in the brain (Wilkinson *et al.*, 1989). Several lines of evidence suggest that UCH-L1 is involved in idiopathic Alzheimer's disease (AD) and Parkinson's disease (PD): (i) UCH-L1 is down-regulated in idiopathic AD and PD (Choi *et al.*, 2004), and in an AD model mouse (Gong *et al.*, 2006); and (ii) UCH-L1 is oxidatively modified in AD brains (Castegna *et al.*, 2002). Substitution of tyrosine for serine at codon 18 (S18Y polymorphism) in the *Uch-l1* gene exerts a protective effect against sporadic AD (Xue & Jia, 2006) and PD (Maraganore *et al.*, 1999). Furthermore, substitution of methionine for isoleucine at codon 93 (I93M mutation) reduces hydrolase activity of UCH-L1 and is linked to a rare autosomal dominant form of familial PD in a German family (Leroy *et al.*, 1998). Although these findings point to a role for UCH-L1 in AD and PD, the physiological role of UCH-L1 in the normal mammalian brain is not fully understood.

UCH-L1 has multiple functions *in vitro*. UCH-L1 removes small adducts or unfolded polypeptides from ubiquitin's C-terminus via hydrolysis (Larsen *et al.*, 1998). In addition, UCH-L1 has ubiquitin-ligase activity on α-synuclein-ubiquitin conjugates (Liu *et al.*, 2002). Apart from enzymatic activity, UCH-L1 acts as a stabilizer of monoubiquitin (Osaka *et al.*, 2003). UCH-L1 is thought to be a therapeutic target for AD; specifically, overexpression of UCH-L1 rescues amyloid β-protein (Aβ)-induced decreases in synaptic plasticity and contextual memory in mice (Gong *et al.*, 2006). Pharmacological suppression of UCH-L1 hydrolase activity (by 70%) is associated with impairment of synaptic transmission, tetanus-induced long-term potentiation (LTP) in the hippocampal CA1 field, and contextual fear memory in mice (Gong *et al.*, 2006). The nonmammalian Aplysia UCH has been identified as an immediate–early gene essential for long-term synaptic facilitation in the nervous system (Hedge *et al.*, 1997).

The aim of the present study was to further characterize the role of UCH-L1 in the mammalian brain. To this end, we utilized the UCH-L1-deficient *gracile axonal dystrophy* (*gad*) mouse, which is a spontaneous mutant with an in-frame deletion in exons 7 and 8 of *Uch-l1* (Saigoh *et al.*, 1999). Expression of the UCH-L1 protein is

undetectable in the central nervous system of *gad* mice (Osaka *et al.*, 2003). In addition, recent analysis in our laboratory suggests that truncated products from the mutant *Uch-l1* are not detected in the *gad* mouse brain (T. Kabuta, unpublished observation). Although *gad* mice exhibit motor paresis beginning at ~12 weeks of age due to axonal degeneration of spinal cord neurons and subsequent degeneration of the spinocerebellar tract (Kikuchi *et al.*, 1990), it is possible to analyse the brain phenotypes of *gad* mice at younger ages when no motor paresis is evident. We found that memory in passive avoidance learning, exploratory behaviour and hippocampal synaptic plasticity are reduced in young *gad* mice (6 weeks of age).

Materials and Methods

Animals

Gad mice were bred at the Experimental Animal Center of the National Institute of Neuroscience, National Center of Neurology and Psychiatry, Tokyo. The original genetic background of *gad* mice was a hybrid of the CBA and RFM strains (Kikuchi *et al.*, 1990). However, *gad* mice were backcrossed to C57BL/6J strain mice 6–18 times before use in the present study. Six-week-old male *gad* mice and wild-type mice generated from heterozygous *gad* mating pairs were used for the experiments. Genotyping was carried out using PCR with the following three primers:

F1, 5′- agcttggagcctgtggtttcaactc-3′;
R1, 5′-tggcagcatcctgaaaaggagaggtg-3′;
R2, 5′-tacagatggccgtccacgttgttga-3′

The reaction conditions were 35 cycles of 94 °C for 20 s, 60 °C for 30 s and 72 °C for 60 s. The wild-type allele produced an 891-bp PCR product, and the *gad* allele produced a 446-bp PCR product. Three to five mice were housed per cage under controlled temperature (25 ± 1 °C) and lighting (12-h light–dark cycle) conditions and provided with food and water *ad libitum*. The experiments were performed in strict accordance with the National Institute of Neuroscience's regulations for animal experimentation, and were approved by the Animal Investigation Committee of the Institute.

Histology

Hematoxylin and eosin (H&E) staining was performed as reported (Kikuchi *et al.*, 1990). For immunohistochemistry, 4-μm-thick paraffin sections were de-paraffinized and pretreated in a microwave oven with 10 mM citrate–NaOH buffer (pH 6.0). After blocking with phosphate-buffered saline containing 1% heat-inactivated normal goat serum and 0.1% [(v/v)] Triton X-100, slides were incubated with an anti-Aβ monoclonal antibody (clone 4G8, 1 : 100 dilution; Signet Laboratories, Dedham, MA, USA) or an antisynaptophysin monoclonal antibody (MAB5258, 1 : 500 dilution; Chemicon, Temecula, CA, USA) and then with Envision+horseradish peroxidase–labelled anti-mouse IgG (DakoCytomation Inc., Carpinteria, CA, USA). Chromogenic detection was performed using the DAB Substrate kit (DakoCytomation Inc.). Sections were examined with a BX51 microscope (Olympus).

Behavioural tests

One-trial passive avoidance tests were performed as described (Yamada *et al.*, 2003). Briefly, a single mouse was introduced into a light compartment of a light–dark box (Muromachi-kikai, Tokyo, Japan). During habituation, mice were allowed to freely explore the box for 5 min with the sliding door between the light and dark compartments open; after that, the mice were returned to their home cage. For conditioning, which was carried out 2 h after habituation, the mice were introduced into the light compartment, the sliding door was closed when both hindlimbs had entered into the dark box, and an electrical footshock was delivered via the floor grid in the dark compartment (300 μA, 3 s duration, using a shock generator–scrambler; Muromachi-kikai). The mice were left in the light–dark box for 5 min and then returned to their home cage. Tests were carried out 2 or 24 h after the conditioning by re-introducing the mice into the light compartment of the light–dark box. The latency time for mice to enter the dark compartment was measured (light–dark latency, with a 5 min cut-off). The tests at 2 and 24 h postconditioning were carried out using different groups of mice.

The pain sensitivity of mice was tested as described (Yamada *et al.*, 2003). Briefly, a series of footshocks of ascending (20, 40, 60, 80, 100 and 130 μA, 1 s duration) and descending (130, 100, 80, 60, 40 and 20 μA, 1 s duration) current were serially delivered to the mice via the floor grid. The input current that induced hindlimb withdraw was recorded. The interfootshock interval was 15 s. This trial was performed six times, and the data were averaged.

Open field tests were performed as we described (Zushida *et al.*, 2007). Briefly, the test was carried out in an arena (a 50 × 50 cm white field surrounded by a 40-cm-high white wall, illuminated with 80 lx) placed in a soundproof box. Mice were placed at the periphery of the arena, and for 5 min the behaviour of the mice was recorded using a digital video camera linked to a computer. Locomotor activity was calculated from this record by Image OF (O'Hara & Co., Ltd, Tokyo, Japan), modified software based on the public domain NIH Image program. Rearing was manually counted.

The light–dark box test was performed as described (Yamada *et al.*, 2002). Briefly, mice were placed into the dark compartment of the light–dark box and were allowed to explore both sides of the light–dark box for 5 min. During these 5 min, three parameters were measured: latency to enter the light compartment, number of entries into the light compartment, and duration in the light compartment.

Electrophysiology

Each 6-week-old male mouse was anaesthetized with halothane, and the brain was quickly removed. Preparation of hippocampal slices for electrophysiology was carried out as reported (Takamatsu *et al.*, 2005; Zushida *et al.*, 2007). Briefly, the hippocampus was isolated from the brain, and transverse slices (400 μm thick) were prepared using a Vibratome 3000 microtome (Vibratome Company, St Louis, MO, USA) in a sucrose-based cutting solution (in mM: sucrose, 234; KCl, 25; NaH_2PO_4, 1.25; $MgSO_4$, 10; $NaHCO_3$, 26; glucose, 11; and $CaCl_2$, 0.5). The slices were maintained at room temperature in artificial cerebrospinal fluid (ACSF; in mM: NaCl, 125; KCl, 4.4; $MgSO_4$, 1.5; NaH_2PO_4, 1.0; $NaHCO_3$, 26; glucose, 10; and $CaCl_2$, 2.5; pH 7.4, 290–300 mOsm/L) continuously bubbled with 95% O_2 and 5% CO_2. A slice was then transferred to the recording chamber and was continuously superfused at 3 mL/min with ACSF maintained at 28–32 °C.

Extracellular field recordings were carried out as reported (Takamatsu *et al.*, 2005). Briefly, field excitatory postsynaptic potentials (fEPSPs) were recorded from CA1 stratum radiatum of the hippocampus using a glass micropipette (1–2 MΩ) filled with ACSF. The electrical signals were amplified using a MultiClamp 700B amplifier (Axon Instruments, Foster City, CA, USA), filtered at 10 kHz, digitized at 10 kHz and acquired with Clampex (ver. 9.2). A bipolar stainless steel stimulating electrode was placed in stratum radiatum at the border between CA2 and CA3 to stimulate the Schaffer collateral pathway. The pulse intensity was adjusted to give 40% of the maximum amplitude in all experiments. Stimulation was carried out in

constant current mode (100 μs duration). The fEPSPs for which the 40% amplitude was > 1 mV were used for data analysis. The strength of synaptic transmission was determined by measuring the rising phase (20–60%) of the fEPSP slope. The average fEPSP slope during the 10 min prior to LTP induction was taken as the baseline, and all values were normalized to this baseline. The baseline stimulation frequency was 0.033 Hz. LTP was induced by applying theta-burst stimulation (TBS; 15 bursts of four pulses at 100 Hz, delivered at an interburst interval of 200 ms) or tetanic stimulation (100 Hz, 1 s, three times with a 20 s interval). Paired-pulse facilitation was induced by delivering two consecutive pulses with a 20-, 50-, 100-, 200- or 400-ms interpulse interval.

Somatic whole-cell patch-clamp recordings were made with a MultiClamp 700B amplifier (Zushida *et al.*, 2007). Pyramidal-shaped neurons in the CA1 pyramidal layer visually identified with differential contrast video microscopy (Hamamatsu Photonics, Hamamatsu, Japan) on an upright microscope (Axioscope, Zeiss, Oberkochen, Germany) were selected for recording. The patch electrodes were 6–10 MΩ when filled with a solution containing (in mM): K gluconate, 132; KCl, 3; HEPES, 10; EGTA, 0.5; $MgCl_2$, 1; sodium phosphocreatine, 12; ATP·Mg, 3; and GTP, 0.5 (pH 7.4 with KOH, 285–290 mOsm/L). We used this solution when measuring membrane potential and input resistance. The input resistance was calculated by injecting a square current pulse (−10 pA) in current-clamp mode. For comparison of synaptic currents at −70 and +40 mV, an internal solution containing (in mM): CsOH, 105; CsCl, 30; HEPES, 10; EGTA, 0.5; $MgCl_2$, 1; sodium phosphocreatine, 12; ATP·Mg, 3; and GTP, 0.5 (pH 7.3 with gluconic acid, 295 mOsm/L) was used. The signal was digitized at one point per 50 μs and stored using Clampex. The resting membrane potential of the cells used in the analysis ranged from −57 to −67 mV, and the series resistance was 3–20 MΩ. Synaptic responses were elicited by electrical stimulation as described for extracellular recording. The pulse intensity was adjusted to elicit excitatory postsynaptic potentials (EPSPs) 40% of the amplitude required for action potential generation in current-clamp mode.

All chemicals and drugs used for electrophysiology were purchased from Sigma with the exception of actinomycin D, which was obtained from Wako Pure Chemicals (Tokyo, Japan). Actinomycin D was dissolved in dimethylsulfoxide at 40 mM, added to ACSF just prior to application at 40 μM, and bath-applied with perfusion. Therefore, the final dimethylsulfoxide concentration was 0.1%.

Western blotting

For analysis of Aβ, the hippocampus was isolated from the brain and snap-frozen in liquid nitrogen. The tissue was homogenized in ice-cold buffer (Tris-HCl, 50 mM; NaCl, 150 mM; EDTA, 5 mM; and Triton X-100, 1%; pH 7.5) containing proteinase inhibitors (Complete, EDTA-free; Roche Applied Science, Indianapolis, IN, USA) and phosphatase inhibitors (Halt phosphatase inhibitor cocktail; Pierce, Rockford, IL, USA), and the homogenate was subjected to SDS-PAGE. Western blotting was carried out as we reported (Kabuta *et al.*, 2006) using anti-Aβ (clone 4G8; Signet Laboratories), anti-UCH-L1 (UltraClone Ltd, UK) and anti-β-actin (Sigma) antibodies. Briefly, immunoreactive signals were visualized with SuperSignal West Femto maximum sensitivity substrate (Pierce) or SuperSignal West Dura extended duration substrate (Pierce) and detected with a chemiluminescence imaging system (FluorChem; Alpha Innotech, San Leandro, CA, USA). Human Aβ 1–42 from Peptide Institute, Inc., Osaka, Japan served as the positive control.

Following extracellular recording, hippocampal slices were retrieved for Western blotting. The dentate gyrus and CA3 region of the slices were cut off, and the remaining CA1 region was snap-frozen in liquid nitrogen. Tissue samples from each slice were homogenized in the same buffer as used for the Aβ analysis, and the homogenate was subjected to SDS-PAGE. The antibodies used were anti-phospho-CREB (serine 133), anti-CREB (Cell Signalling Technology, Inc., Danvers, MA, USA), anti-cAMP-dependent protein kinase (protein kinase A; PKA) regulatory subunit RIα and RIIα (BD Biosciences, San Jose, CA, USA), anti-UCH-L1 (UltraClone Ltd) and anti-β-actin (Sigma). Immunoreactive signals were visualized as described for the Aβ analysis. The signal intensity was quantified by densitometry using FluoChem software (Alpha Innotech).

Data and statistical analysis

Numerical data are expressed as the mean ± SEM. The two-tailed Student's *t*-test was used for comparison between wild-type mice and *gad* mice. Repeated-measures one-way ANOVA was used to analyse whether footshock and exposure to an open field arena had significant effects within a genotype in passive avoidance and open field tests, respectively. ANOVA with the Bonferroni–Dunn test was used to compare the three data groups in the pCREB analysis.

Results

Structural abnormalities were not detected in the cerebrum and hippocampus of young gad mice

Before behavioural analysis, we first examined whether there were any histological abnormalities in the cerebral cortex and hippocampus of 6-week-old *gad* mice. It has been reported that the thalamus is not impaired in *gad* mice (Kikuchi *et al.*, 1990), but there is no report on the cortex and limbic system. Figure 1A–D shows H&E staining of coronal brain sections (at bregma level −1.7 mm) from a wild-type mouse (Fig. 1A and C) and *gad* mouse (Fig. 1B and D; 6 weeks of age). We could not detect any visible abnormalities, such as atrophy or lack of cells, in the hippocampus or cortex of *gad* mice ($n = 2$). One anatomical characteristic of *gad* mice is spheroid structures in the medulla and spinal cord that are thought to be degenerating axons (Kikuchi *et al.*, 1990). We did not find this aberration in the hippocampus or cortex of *gad* mice (Fig. 1A–D). We also examined other brain regions in sections cut at bregma levels 2.5, 1.0, −3.0 and −6.0 mm, and no outstanding abnormalities were evident in the *gad* mice (data not shown). In addition, we carried out immunohistochemical staining using antisynaptophysin. This antibody stains presynaptic sites and thus the staining pattern would be expected to be different in *gad* mice if there was noticeable axonal degeneration. Typical punctate synaptophysin staining was obtained in both wild-type (Fig. 1E and G) and *gad* (Fig. 1F and H) mice. We could not detect any visible differences in the staining of the hippocampus between wild-type and *gad* mice. These results suggest that structural impairment of the brain at a macroanatomical level is not evident in 6-week-old *gad* mice.

Axonal degeneration promotes accumulation of Aβ in the medulla and spinal cord of *gad* mice (Ichihara *et al.*, 1995). Consistent with the lack of spheroid structures in the cortex and hippocampus, we did not find abnormal accumulation of Aβ in these brain regions in *gad* mice up to 12 weeks of age (immunohistochemical analysis using an antibody to Aβ; data not shown). Furthermore, we examined nonfibrillar Aβ by Western blotting. We could not detect any significant bands in the samples from wild-type and *gad* mouse hippocampi when blotting with anti-Aβ (Fig. 1I, upper panel). Authentic human Aβ (the right two lanes, a positive control) blotted

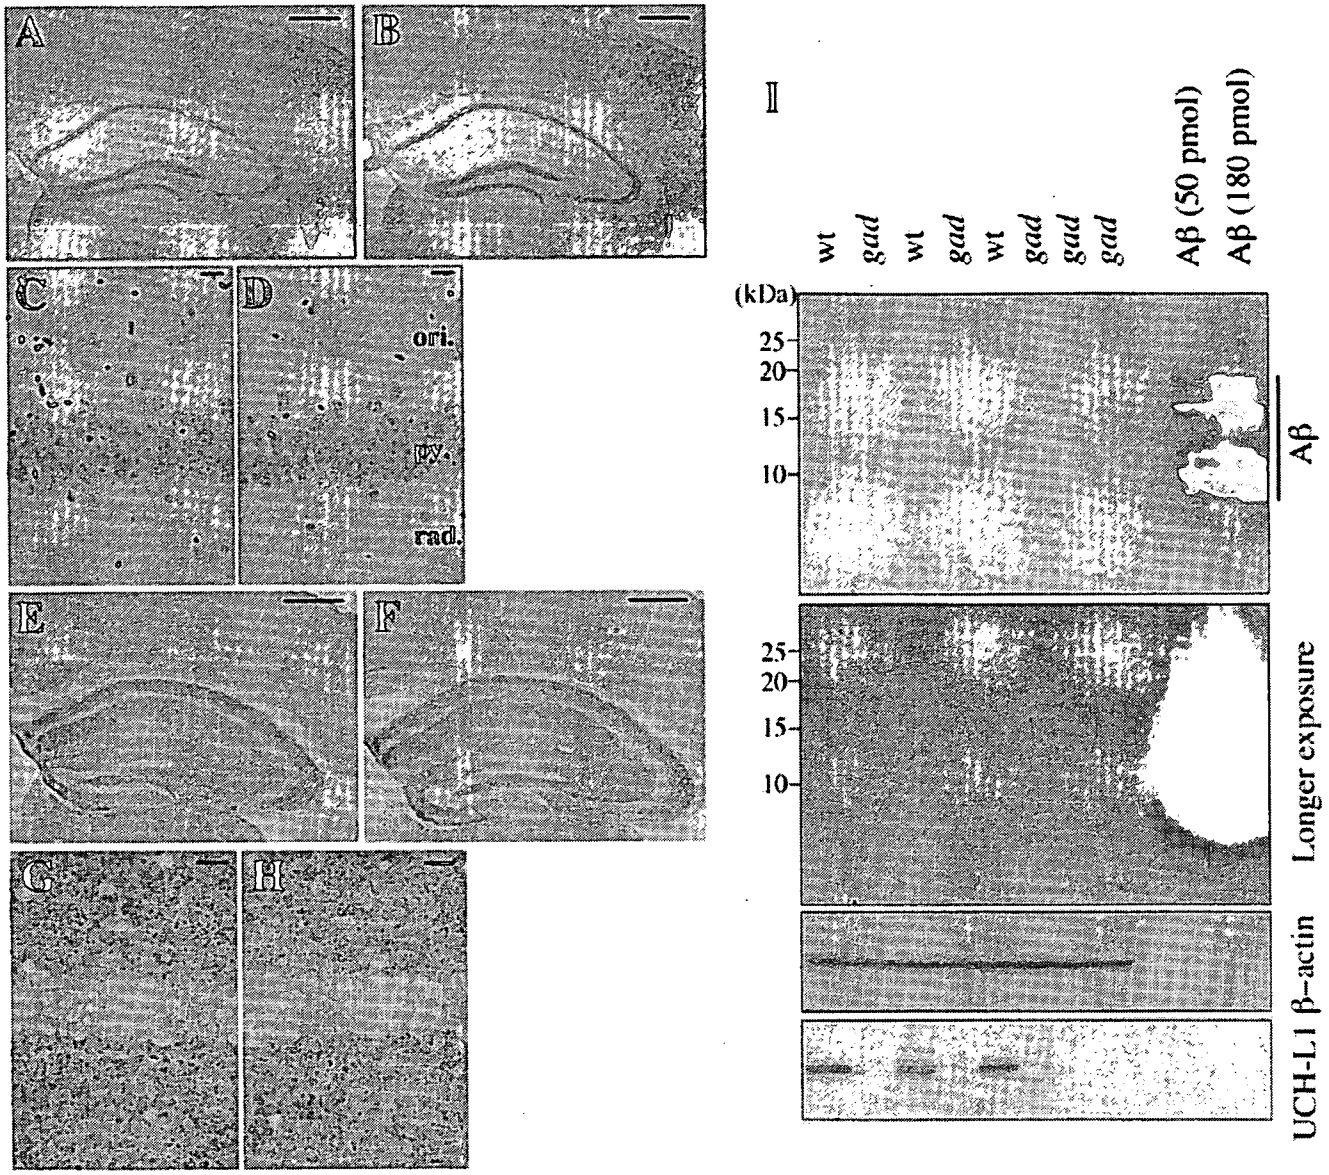

FIG. 1. Six-week-old *gad* mice have normal brain histology. (A–D) H&E staining of coronal brain sections from (A and C) a 6-week-old wild-type (wt) mouse and (B and D) a 6-week-old *gad* mouse. (C and D) A higher magnification of the hippocampal CA1 field. ori., stratum oriens; py., pyramidal cell layer; rad., stratum radiatum. (E–H) Synaptophysin immunohistochemistry in coronal brain sections from a six-week-old wt mouse (E and G) and a six-week-old *gad* mouse (F and H). (G and H) A higher magnification of the hippocampal CA1 field. (I) Western blotting of samples prepared from the hippocampi of three wt and five *gad* mice. Antibodies against Aβ, β-actin and UCH-L1 were used. Authentic Aβ was used as a positive control. A short exposure is shown in the upper panel; a longer exposure is shown below. Molecular size markers (kDa) are shown on the left. Scale bars, 500 μm (A, B, E and F), 20 μm (C, D, G and H).

densely on the same membrane. After a longer exposure (Fig. 1I) we could detect certain bands, but there was no band that was significantly increased in *gad* mice compared with wild-type mice. Blots using antiβ-actin and anti-UCH-L1 were carried out to confirm the sample load and genotype, respectively (Fig. 1I).

Lack of UCH-L1 in mice impaired memory maintenance in the passive avoidance test and exploratory behaviour for a novel environment

Next, we examined whether lack of UCH-L1 had a detectable impact on mouse behaviour. For this purpose, we carried out one-trial passive avoidance tests. Figure 2A shows the performance of wild-type and *gad* mice in this test. After habituation to the light–dark box, mice were conditioned with an electrical footshock when they entered the dark compartment. We then tested their ability to avoid the dark compartment 24 h after the conditioning footshock. The footshock significantly prolonged the light–dark latency in wild-type mice (comparison of the conditioning and test sessions $P = 0.003$, $F = 14.6$, $n = 12$; repeated-measures ANOVA). In contrast, the light–dark latency was not significantly affected in *gad* mice (comparison of the conditioning and test sessions using repeated-measures ANOVA, $P = 0.2437$, $F = 1.556$, $n = 10$), suggesting that memory function, as assessed by this test, is impaired in *gad* mice. In

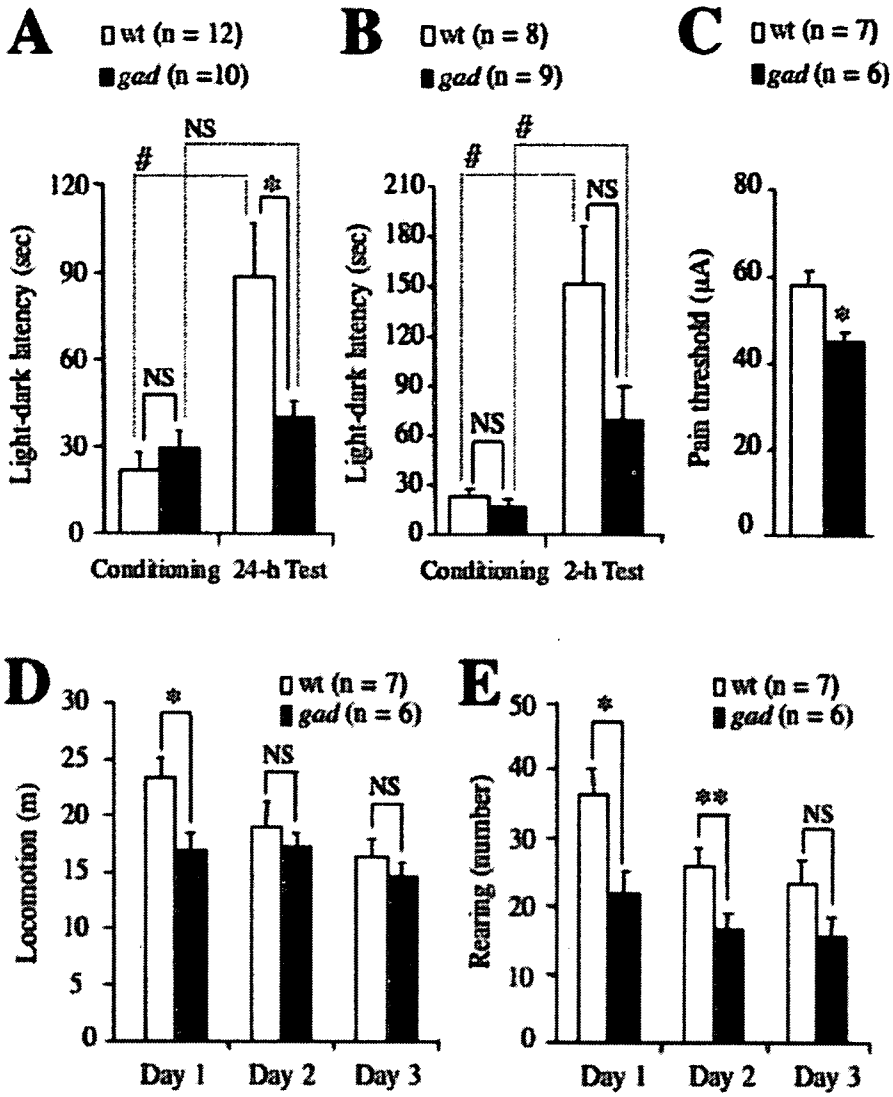

FIG. 2. Impairment of memory maintenance and exploratory behaviour in *gad* mice. (A and B) Light–dark latency of mice in a one-trial passive avoidance test. After habituation to a light–dark box, mice were conditioned with an electrical footshock when they entered the dark compartment (Conditioning). At (A) 24 h or (B) 2 h after the footshock, the mice were reintroduced into the light–dark box and the time for mice to enter the dark compartment (light–dark latency) was measured (Test). $^{*}P = 0.028$; NS, not significant; two-tailed Student's *t*-test (solid lines). $^{\#}P < 0.020$; NS, not significant, repeated-measures one-way ANOVA (dotted lines). (C) Pain sensitivity of the mice was measured by applying a series of electrical footshocks. $^{*}P = 0.002$, two-tailed Student's *t*-test. (D) Locomotor activity of wild-type and *gad* mice in an open field arena. The mice were introduced into the arena for the first time on day 1. $^{*}P = 0.023$, two-tailed Student's *t*-test. (E) Rearing frequency of wild-type and *gad* mice in an open field arena. $^{*}P = 0.014$, $^{**}P = 0.021$; two-tailed Student's *t*-test.

addition, the light–dark latency in the 24-h test session differed significantly between the wild-type and *gad* mice ($P = 0.028$; two-tailed Student's *t*-test). We next conducted a test session 2 h after conditioning to test whether learning ability was impaired in *gad* mice shortly after conditioning. In the test 2 h after conditioning (Fig. 2B), the footshock had a significant effect on the light–dark latency in both wild-type and *gad* mice ($P = 0.0147$, $F = 10.356$, $n = 8$ for wild-type mice; $P = 0.0199$, $F = 8.407$, $n = 9$ for *gad* mice; repeated-measures ANOVA). The average latency in the 2-h test session did not differ significantly between the wild-type and *gad* mice ($P = 0.074$; two-tailed Student's *t*-test). These results suggest that *gad* mice are able to learn but maintenance of memory is reduced. Because the pain sensitivity of *gad* mice was greater than that of wild-type mice (Fig. 2C; $P = 0.002$ with two-tailed Student's *t*-test), the footshock used for conditioning was indeed an aversive stimulus in *gad* mice.

Next, we carried out the open field test. Mice were exposed to an open field arena for the first time on day 1 (Fig. 2D). The wild-type mice explored the novel environment and showed high locomotor activity (Fig. 2D). Locomotor activity was reduced upon re-exposure of wild-type mice to the same arena on days 2 and 3 because they remembered the arena, and thus the novelty was reduced ($P = 0.024$, $F = 12.928$, $n = 7$; repeated-measures ANOVA). In contrast, locomotor activity was not significantly decreased in *gad* mice ($P = 0.392$, $F = 1.030$, $n = 6$; repeated-measures ANOVA). The locomotor activity on day 1 differed significantly between wild-type and *gad* mice ($P = 0.023$; two-tailed Student's *t*-test), but the activity on day 2 or 3 did not ($P = 0.500$ and 0.446 for days 2 and

3, respectively). To determine whether the difference in locomotor activity on day 1 was due to reduced exploratory behaviour in *gad* mice, we measured the frequency of rearing, a typical exploratory behaviour (Lever *et al.*, 2006; Fig. 2E). Similar to locomotor activity, upon re-exposure rearing frequency decreased in wild-type mice ($P = 0.009$, $F = 14.257$, $n = 7$; repeated-measures ANOVA) but not in *gad* mice ($P = 0.131$, $F = 2.503$, $n = 6$; repeated-measures ANOVA). The rearing frequency on days 1 and 2 differed significantly between wild-type and *gad* mice ($P = 0.014$ and 0.021 for days 1 and 2, respectively; two-tailed Student's *t*-test), but the activity on day 3 did not ($P = 0.093$). These results suggest that exploratory behaviour in a novel environment is reduced in *gad* mice.

Although these data apparently suggest that memory in passive avoidance learning and exploratory behaviour are reduced in young *gad* mice, there is a possibility that the anxiety state of *gad* mice is altered. Alterations in the anxiety state can affect memory (Bouton *et al.*, 1990) and the response to novel environments. To measure anxiety, we performed a light–dark box test. In this test, mice usually avoid the light compartment. Therefore, the level of anxiety can be measured as the latency to move into the light compartment and the duration of time in the light compartment (Yamada *et al.*, 2002). Because the passive avoidance test also utilizes these properties, performance in the light–dark test is important for interpreting the results from the passive avoidance test. The time required for the mice to step into the light compartment when introduced into the dark compartment (dark-light latency; Fig. 3A), the time the mice spent in the light compartment (Fig. 3A) and the number of times the mice crossed between compartments (Fig. 3B) did not differ significantly between wild-type and *gad* mice ($P = 0.834$, 0.417 and 0.109, respectively; two-tailed Student's *t*-test). These results suggest that anxiety state, as assessed by this test, was not obviously altered in *gad* mice. Therefore we concluded that the impairments in passive avoidance learning and exploratory behaviour were not due to alterations in the anxiety state.

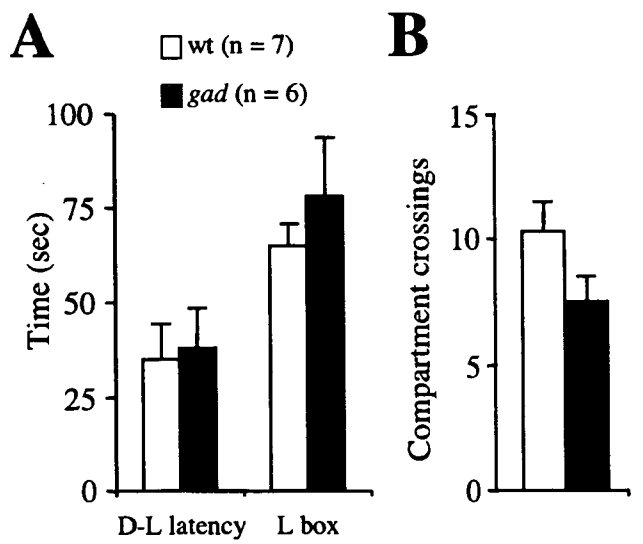

FIG. 3. Wild-type and *gad* mice performed similarly in the light–dark box test. (A) Dark–light (D-L) latency and duration of time in the light compartment (L box). (B) Number of crossings between the two compartments.

Impairment of a transcription-dependent component of LTP in gad mice

We tested whether the lack of UCH-L1 affects neuronal function by measuring LTP at Schaffer collateral synapses onto CA1 pyramidal neurons in hippocampal slice preparations. LTP is believed to be a synaptic mechanism underlying memory and learning (Bliss & Collingridge, 1993). The CA1 synapse was selected because this brain region is involved in spatial memory (Morris *et al.*, 1982) and passive avoidance memory (Bevilaqua *et al.*, 1997; Impey *et al.*, 1998). In wild-type slices, TBS induced robust LTP at CA1 synapses (Fig. 4A), as reported for C57BL/6J mice (Nguyen & Kandel, 1997; Nguyen *et al.*, 2000). In contrast, TBS-induced LTP was attenuated in *gad* mice beginning ~20 min post-TBS (Fig. 4A). At 45 min post-TBS, normalized synaptic responses were significantly greater in wild-type slices (1.87 ± 0.08, $n = 7$) than in *gad* slices (1.36 ± 0.07, $n = 6$; $P = 0.001$, two-tailed Student's *t*-test). Impairment of LTP in *gad* mice depended on the stimulation pattern. Tetanus-induced LTP was identical in wild-type and *gad* mice (Fig. 4B; normalized fEPSP slopes at 45 min post-tetanus: wild-type, 1.81 ± 0.16, $n = 5$; *gad*, 1.86 ± 0.25, $n = 5$).

Stimulus–output curves (Fig. 5A) and paired-pulse facilitation (Fig. 5B) of CA1 synapses were essentially identical in wild-type and *gad* mice. The latter result suggests that a postsynaptic, rather than presynaptic, mechanism is involved in impairment of TBS-induced LTP in *gad* mice. LTP at this synapse is dependent on postsynaptic NMDA receptors (Harris *et al.*, 1984; Larson & Lynch, 1988). Therefore, we tested whether NMDA receptor activity was reduced in *gad* mice using patch-clamp recordings. For this purpose, we recorded Schaffer collateral–CA1 synaptic responses in neurons voltage-clamped to −70 and +40 mV in the presence of picrotoxin (50 μM). The amplitude of the synaptic response recorded at +40 mV at 100 ms poststimulation was normalized to the peak amplitude of the response at −70 mV to estimate the ratio of NMDA-mediated to non-NMDA-mediated currents (Fig. 5D). Because superfusion of the slices with picrotoxin frequently elicited epileptiform activity (data not shown), three to five synaptic responses without epileptiform activity were selected and averaged. The ratio was identical in wild-type and *gad* mice (0.45 ± 0.05, $n = 5$ and 0.43 ± 0.05, $n = 7$ for wild-type and *gad* mice, respectively; two-tailed Student's *t*-test). Therefore, attenuation of synaptic NMDA receptor activity does not account for reduced LTP in *gad* mice. Resting membrane potential and input resistance of CA1 pyramidal neurons did not differ substantially between wild-type and *gad* mice [resting membrane potential, -60.1 ± 0.4 mV for wild-type mice ($n = 20$) and -60.0 ± 0.6 mV for *gad* mice ($n = 20$); input resistance, 163 ± 9.6 for wild-type mice ($n = 16$) and 175 ± 10.8 for *gad* mice ($n = 13$); results obtained from the records using potassium-gluconate pipette solution].

CA1 LTP is composed of early and late temporal phases (Nguyen *et al.*, 1994; Abel *et al.*, 1997; Nguyen & Kandel, 1997). The former is induced mainly by an increase in the number of AMPA-type glutamate receptors at the synapse (reviewed in Malinow & Malenka, 2002) whereas the latter is induced by new protein synthesis from transcription of new mRNA (Nguyen *et al.*, 1994) and/or local protein synthesis from previously expressed mRNA (Bradshaw *et al.*, 2003). Because no obvious changes in the early phase of LTP (up to ~20 min post-TBS) were observed in *gad* mice, we tested whether the late phase is occluded in *gad* mice. For this purpose, we applied actinomycin D, a transcription inhibitor, to the slices and compared suppression of TBS-induced LTP in wild-type and *gad* mice. In wild-type mice, the maintenance of TBS-induced LTP was suppressed by actinomycin D (Fig. 6A). The normalized fEPSP slope at 45 min

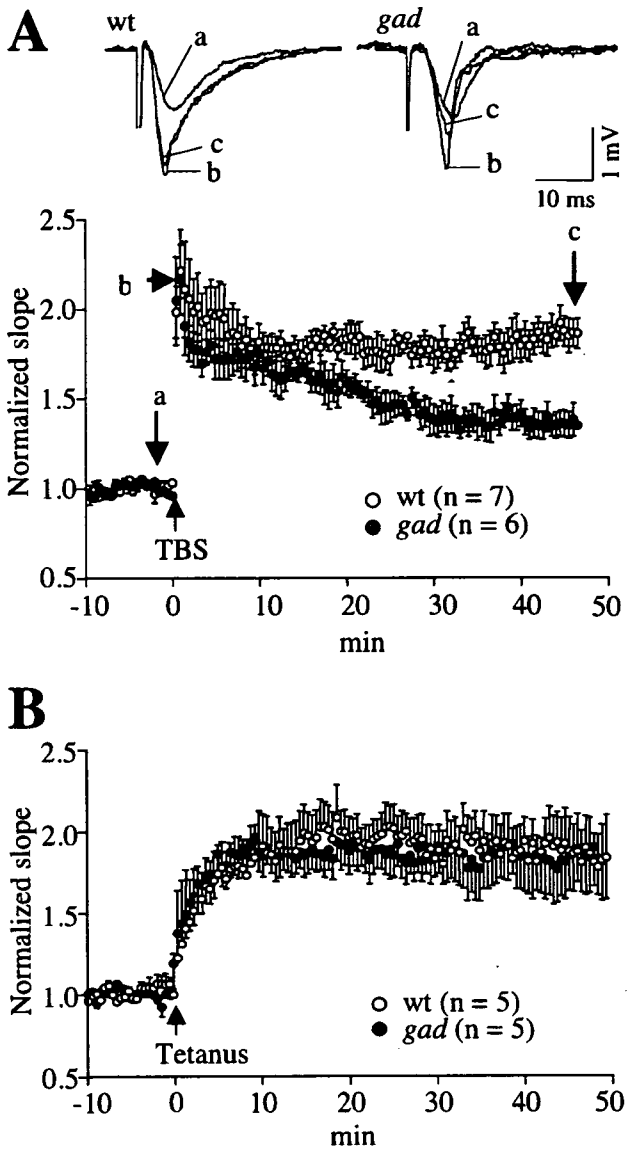

FIG. 4. TBS-induced LTP in area CA1 of the *gad* mouse hippocampus was impaired. (A) LTP induced by TBS in wild-type (○) and *gad* (●) mice. The fEPSP slope was normalized to baseline (pre-TBS) values. Typical fEPSP traces are shown above. Traces were recorded (a) just before TBS, (b) immediately after TBS and (c) 45 min after TBS. (B) Tetanus-induced LTP was identical in wild-type and *gad* mice.

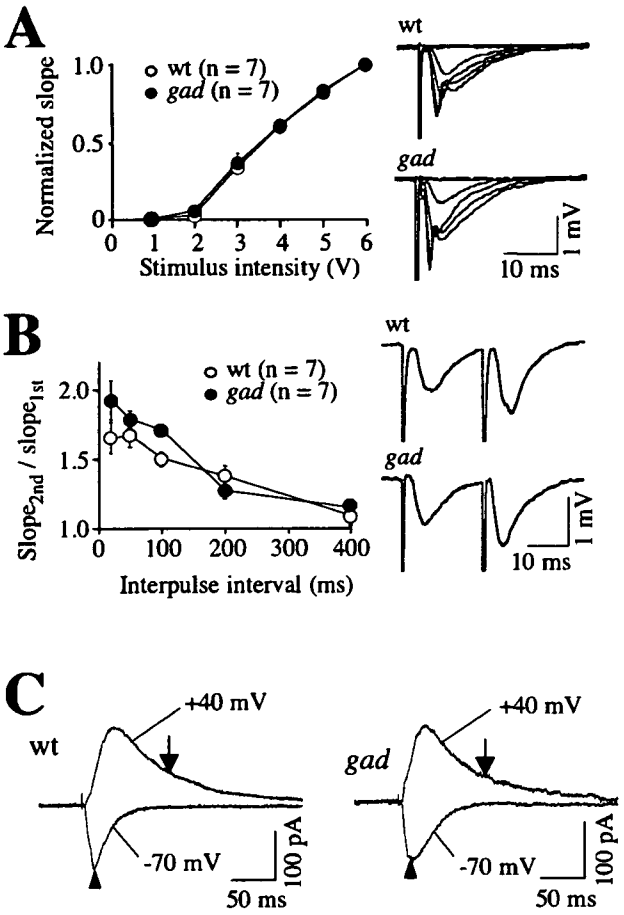

FIG. 5. Stimulus–output curves, paired-pulse facilitation and NMDA receptor–mediated currents were similar in wild-type and *gad* mice. (A) The relation between stimulus intensity and the slope of the fEPSP was identical in wild-type and *gad* mice. For each slice, fEPSP slopes elicited by six different stimulus intensities (1–6 V; sample traces in the right panel) were normalized to the value obtained using 6-V stimulation, and then normalized values were averaged. (B) Paired-pulse facilitation of fEPSPs did not differ substantially between wild-type and *gad* mice. (C) The ratio of NMDA receptor-mediated currents to non-NMDA receptor-mediated currents was identical in wild-type and *gad* mice. Patch-clamp recordings from neurons voltage-clamped to −70 and +40 mV. The arrowhead indicates the peak of the non-NMDA receptor-mediated current, and the arrow indicates 100 ms poststimulation for the NMDA receptor-mediated current; current amplitudes at these points were used for the ratio.

post-TBS was 1.43 ± 0.07 (n = 5) in the presence of actinomycin D, and this value differed significantly from that in wild-type hippocampal slices without actinomycin D (1.87 ± 0.08, P = 0.003; two-tailed Student's t-test). This result agrees with a previous report (Nguyen & Kandel, 1997). In contrast, TBS-induced LTP in *gad* mice was insensitive to actinomycin D (Fig. 6B). The normalized fEPSP slope at 45 min post-TBS was 1.36 ± 0.04 (n = 5) in the presence of actinomycin D and did not differ significantly from the value in *gad* hippocampal slices without actinomycin D (1.36 ± 0.07, P = 0.948; two-tailed Student's t-test). These results suggest that a transcription-dependent component of LTP is impaired in *gad* mice. In both wild-type and *gad* mice, actinomycin D did not affect the baseline fEPSP slope (without TBS) up to 80 min postapplication (Fig. 6C and D).

CREB phosphorylation was altered in gad mice

Late-phase LTP in the hippocampal CA1 field requires transcription elicited by phosphorylation of serine 133 on cAMP response element binding protein (CREB; Nguyen *et al.*, 1994). In addition, Aplysia UCH is involved in persistent activation of PKA during long-term synaptic facilitation (Hedge *et al.*, 1997). From these reports and our experiments using actinomycin D above, we suspected that phosphorylated CREB (pCREB)-induced transcription is disrupted in *gad* mice. To address this, we analysed pCREB in the CA1 field of slices used

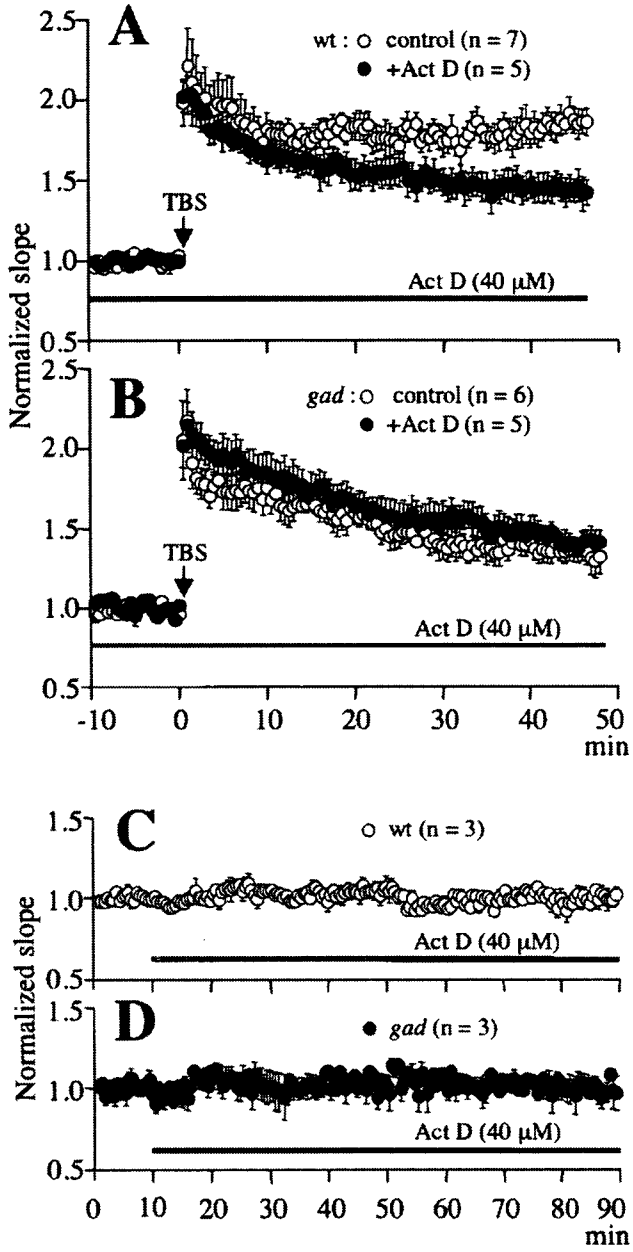

FIG. 6. Transcription-dependent LTP was impaired in *gad* mice. (A and B) Actinomycin D (Act D) suppressed late-phase LTP in (A) wild-type mice but (B) had no effect in *gad* mice. Act D was applied 10 min before LTP induction and was continuously applied until 50 min post-TBS. LTP in the absence of Act D (control) has been reproduced from Fig. 4. (C and D) Without TBS, Act D had no effect on the normalized fEPSP slope in either (C) wild-type or (D) *gad* mice.

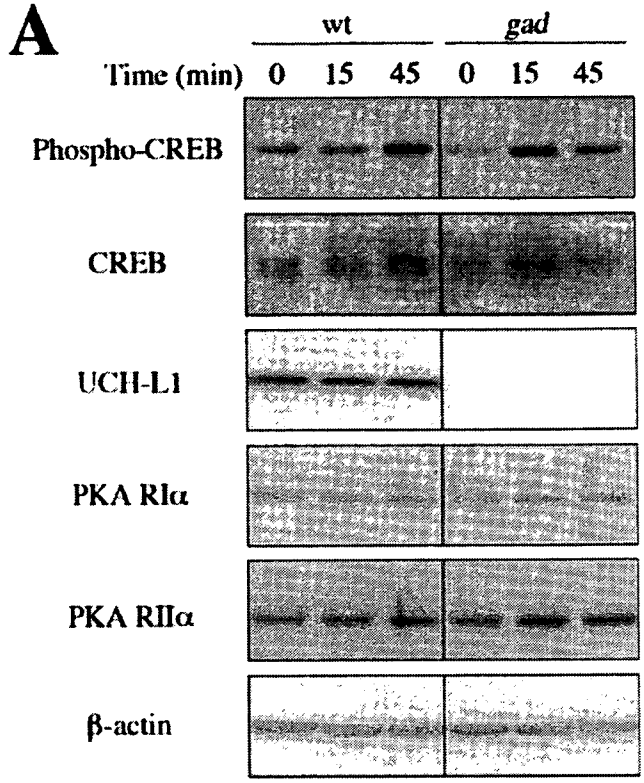

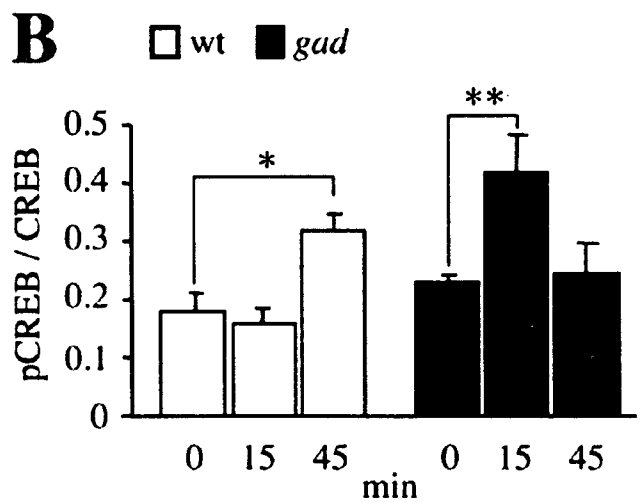

FIG. 7. CREB phosphorylation was altered in *gad* mice. (A) Western blotting of samples prepared from hippocampal slices recovered pre-TBS (0), 15 min post-TBS (15) or 45 min post-TBS (45). Primary antibodies are indicated to the left of the blots. Similar results were obtained at each time point in six slices from wild-type mice and five slices from *gad* mice. (B) The normalized band density of pCREB to CREB at time 0 (pre-TBS), 15 min and 45 min post-TBS in wild-type ($n = 5$) and *gad* ($n = 4$) mice. $^{*}P = 0.012$ and $^{**}P = 0.014$, Bonferroni–Dunn test.

for electrophysiological recording by Western blotting (Fig. 7A). In wild-type mice, pCREB levels at 15 min post-TBS did not differ from pre-TBS levels, but at 45 min post-TBS levels were increased relative to pre-TBS levels. The onset of CREB phosphorylation (45 min postconditioning) is in agreement with a previous report (Ahmed & Frey, 2005). In *gad* mice, however, pCREB levels were increased at 15 min post-TBS but not maintained at 45 min post-TBS (Fig. 7A). Unphosphorylated CREB levels were similar among samples (Fig. 7A). Similar results were obtained in slices from five wild-type and four *gad* mice. In each set of slices, the band density of pCREB was normalized to that of CREB and the values were averaged (Fig. 7B). In wild-type mice (Fig. 7B), the normalized pCREB levels at 15 min post-TBS did not differ significantly from pre-TBS levels

($P = 0.656$; Bonferroni–Dunn test) but at 45 min post-TBS pCREB levels were significantly higher than pre-TBS levels ($P = 0.012$). In *gad* mice (Fig. 7B), pCREB levels were significantly higher at 15 min post-TBS ($P = 0.014$), but at 45 min post-TBS pCREB levels were not significantly different from pre-TBS levels ($P = 0.393$). These results suggest that the onset and persistence of CREB phosphorylation are altered in *gad* mice.

In Aplysia, serotonin stimulation that induces synaptic plasticity increases expression of UCH by about five-fold. The increased UCH expression stimulates proteasomal degradation of the PKA regulatory subunit N4, thereby inducing persistent PKA activity (Hedge *et al.*, 1997). To determine whether this process also exists in mice, we analysed UCH-L1 and PKA regulatory subunits Iα and IIα in the CA1 field of hippocampal slices by Western blotting. As Fig. 7A shows, the level of UCH-L1 was not obviously affected by TBS at either 15 or 45 min post-TBS in wild-type mice. For quantitative analysis, the band density of UCH-L1 was normalized to that of β-actin and the normalized value was then further normalized to pre-TBS values. At 15 and 45 min post-TBS, the normalized values were 1.00 ± 0.24 ($n = 5$) and 1.06 ± 0.21 ($n = 5$), respectively, confirming that UCH-L1 levels were unchanged. Similarly, TBS-induced changes in the levels of PKA regulatory subunit Iα and IIα were also not apparent in either type of mouse (Fig. 7A). For example, the relative band-density of PKA IIα normalized to β-actin was 1.03 ± 0.14 (15 min post-TBS) and 1.06 ± 0.12 (45 min post-TBS) for wild-type mice ($n = 5$). In *gad* mice ($n = 4$), values were 1.02 ± 0.20 (15 min post-TBS) and 1.01 ± 0.25 (45 min post-TBS). For pre-TBS, the relative band-density of PKA IIα normalized to β-actin also did not differ between wild-type and *gad* mice [the normalized value for *gad* mice/the normalized value for wild-type mice was 0.96 ± 0.10 ($n = 4$)].

Discussion

In this study, we demonstrated that UCH-L1 is required for (i) maintenance of memory in a passive avoidance test and exploratory behaviour in a novel environment, and (ii) a transcription-dependent component of TBS-induced LTP in area CA1 of the hippocampus. UCH-L1 may be essential in transcription-dependent TBS-LTP because it maintains the integrity of TBS-induced CREB phosphorylation. No outstanding forebrain atrophy or aberrant structures were evident in 6-week-old *gad* mice at the level of the light microscope. Thus, the functional abnormalities caused by the lack of UCH-L1 occurred in the absence of any detectable gross structural abnormalities in the brain. However, abnormalities in neuron morphology, such as spine morphology or density, remain a possibility in *gad* mice.

Several studies suggest that synaptic and memory abnormalities precede neuronal cell death in AD (Yao *et al.*, 2003) and in AD model mice (Chapman *et al.*, 1999; Freir *et al.*, 2001; Snyder *et al.*, 2005; Shemer *et al.*, 2006), which supports the hypothesis that synapses may be an initial target in AD (Small *et al.*, 2001; Selkoe, 2002). Aβ is thought to be one of the major players that disrupt synaptic function (reviewed in Selkoe, 2002). Because we have shown here that UCH-L1 is essential for memory maintenance, exploratory behaviour and a particular form of hippocampal LTP, it is possible that the AD-associated reduction in UCH-L1 (Choi *et al.*, 2004) further exacerbates the synaptic and memory deficits induced by Aβ accumulation. In addition, glutamate-induced CREB phosphorylation is decreased by Aβ treatment of cultured hippocampal neurons (Vitolo *et al.*, 2002). Thus, accumulation of Aβ and reduction of UCH-L1 may act cooperatively to disrupt CREB phosphorylation. The recent finding that introduction of exogenous UCH-L1 into AD model mice rescues synaptic and memory deficits supports this possibility (Gong *et al.*, 2006).

It should be noted that memory deficits are already evident in young *gad* mice (6 weeks of age). Analysis of AD model mice has shown that the onset of the behavioural phenotype is generally much slower. For example, deficits in visible platform recognition become evident by 9 months of age, and deficits in sensorimotor tasks are clearly manifest by 14 months in the Tg2579 transgenic AD model mice (King & Arendash, 2002). Impairments in passive avoidance and small-pool performance are marked only at 18 and 25 months of age in the APP23 transgenic AD model mice (Kelly *et al.*, 2003). It has not been reported whether UCH-L1 is down-regulated in these model mice. In the APP/PS1 mouse model of AD, on the other hand, relatively young (3- to 4-month-old) mice have impaired contextual learning (Trinchese *et al.*, 2004; Gong *et al.*, 2006), and reduced hippocampal UCH activity is evident at 4–6 months of age (Gong *et al.*, 2006). Whether the onset of the reduction in the hydrolase activity is synchronous with the onset of impaired contextual learning in the APP/PS1 mouse is unknown. This information is necessary to further verify the involvement of UCH-L1 in memory deficits associated with AD and in AD model mice.

Impairment of memory in *gad* mice was associated with impaired transcription-dependent LTP in the hippocampus. Because LTP is a well-known cellular mechanism of memory (reviewed in Bliss & Collingridge, 1993), it is reasonable to speculate that impaired LTP is one of the mechanisms underlying the memory deficits in *gad* mice. Our results provide a possible mechanistic link between the lack of UCH-L1 and impaired LTP: alteration of CREB phosphorylation. Proper timing and persistence of CREB phosphorylation are essential for the gene expression required to maintain LTP in area CA1 of the hippocampus (Impey *et al.*, 1996). After conditioning in the passive avoidance test, cAMP response element-mediated transcription is induced in hippocampal area CA1 (Impey *et al.*, 1998). Thus, the alteration of CREB phosphorylation and subsequent failure to maintain LTP might be responsible for reduced performance of *gad* mice in the passive avoidance test. However, LTP at hippocampal CA1 synapses is dependent on NMDA receptors (Harris *et al.*, 1984; Larson & Lynch, 1988). Phosphorylation of CREB is also NMDA receptor-dependent (Ahmed & Frey, 2005). This type of LTP occurs in various brain regions (reviewed in Martin *et al.*, 2000), and UCH-L1 is expressed in almost all brain regions. Therefore, impaired LTP in other brain regions may also be involved in the poor performance of *gad* mice in the passive avoidance test and other behavioural tests. Postsynaptically, the ubiquitin–proteasome system is involved in activity-dependent changes in postsynaptic protein composition and signalling (Ehlers, 2003; reviewed in Yi & Ehlers, 2007). UCH-L1 has *in vitro* enzymatic activity that exposes the free C-terminus of ubiquitin, which is required for protein ubiquitination (Larsen *et al.*, 1998), and monoubiquitin levels are decreased in *gad* mouse brain (Osaka *et al.*, 2003).

In conclusion, we report that UCH-L1 is required for the maintenance of memory in passive avoidance learning, exploratory behaviour and hippocampal CA1 LTP in mice. We propose that UCH-L1-mediated maintenance of the temporal integrity and persistence of CREB phosphorylation is required for CA1 LTP.

Received January 8, 2008; Revised and Accepted January 30, 2008

Parkinson's disease (PD) is a neurodegenerative disorder characterized by loss of dopaminergic neurons. The I93M mutation in ubiquitin C-terminal hydrolase L1 (UCH-L1) is associated with familial PD, and we have previously shown that the I93M UCH-L1-transgenic mice exhibit dopaminergic cell loss. Over 90% of neurodegenerative diseases, including PD, occur sporadically. However, the molecular mechanisms underlying sporadic PD as well as PD associated with I93M UCH-L1 are largely unknown. UCH-L1 is abundant (1–5% of total soluble protein) in the brain and is a major target of oxidative/carbonyl damage associated with sporadic PD. As well, abnormal microtubule dynamics and tubulin polymerization are associated with several neurodegenerative diseases including frontotemporal dementia and parkinsonism linked to chromosome 17. Here we show that familial PD-associated mutant UCH-L1 and carbonyl-modified UCH-L1 display shared aberrant properties: compared with wild-type UCH-L1, they exhibit increased insolubility and elevated interactions with multiple proteins, which are characteristics of several neurodegenerative diseases-linked mutants. Circular dichroism analyses suggest similar structural changes in both UCH-L1 variants. We further report that one of the proteins interacting with UCH-L1 is tubulin, and that aberrant interaction of mutant or carbonyl-modified UCH-L1 with tubulin modulates tubulin polymerization. These findings may underlie the toxic gain of function by mutant UCH-L1 in familial PD. Our results also suggest that the carbonyl modification of UCH-L1 and subsequent abnormal interactions of carbonyl-modified UCH-L1 with multiple proteins, including tubulin, constitute one of the causes of sporadic PD.

INTRODUCTION

Parkinson's disease (PD) is the most common neurodegenerative movement disorder and is characterized by progressive cell loss confined mostly to dopaminergic neurons in the substantia nigra pars compacta. The I93M mutation in ubiquitin C-terminal hydrolase L1 (UCH-L1) was reported in a German family with dominantly inherited PD (1). To assess the correlation of the I93M mutation and pathogenesis of PD, we have previously generated UCH-L1^{I93M}-transgenic mice. These mice exhibited progressive dopaminergic cell loss in the substantia nigra (2), suggesting that the I93M mutation in UCH-L1 is a causative mutation for PD. The S18Y polymorphism in UCH-L1 has been reported to be associated with decreased risk of PD (3). However, it has also been reported that S18Y is not associated with risk of PD (4).

UCH-L1 is abundant (1–5% of total soluble protein) in the brain (5) and is thought to hydrolyse polymeric ubiquitin and ubiquitin conjugates to monoubiquitin (6). UCH-L1 has also been reported to act as a ubiquitin ligase *in vitro* (7). In

*To whom correspondence should be addressed. Tel: +81 423461715; Fax: +81 423461745; Email: kabuta@ncnp.go.jp; clockkab@ybb.ne.jp (T.K.); wada@ncnp.go.jp (K.W.)

addition to these enzymatic activities, we have found that UCH-L1 binds to and stabilizes monoubiquitin in neurons (8). Our previous studies using circular dichroism (CD) and small-angle neutron scattering strongly suggested that the I93M mutation in UCH-L1 alters the conformation of UCH-L1 (9,10). We have previously shown that mice deficient in UCH-L1 do not exhibit progressive dopaminergic cell loss, in contrast to UCH-L1^{I93M}-transgenic mice (2,8,11), suggesting that a loss or decrease in the level of UCH-L1 is not the main cause of PD, and that UCH-L1^{I93M}-associated PD is caused by an acquired toxicity. Thus, although the hydrolase activity of UCH-L1^{I93M} is decreased (1,9), this decreased activity may not be a major cause of PD.

Increased oxidative stress is associated with neurodegenerative diseases (12,13). In sporadic PD brains, UCH-L1 is a major target of carbonyl formation (12), which is the most widely used marker for oxidative damage to proteins. UCH-L1 has also been identified as a component of several inclusion bodies characteristic of neurodegenerative diseases, including Lewy bodies (14). These findings suggest that UCH-L1 and its modification by carbonyl formation are involved in the cause of sporadic PD. Despite the fact that the majority of PD cases occur sporadically, the molecular mechanisms underlying the causes of sporadic PD, as well as UCH-L1^{I93M}-associated PD, are largely unknown. Moreover, the biochemical properties of UCH-L1^{I93M} and carbonyl-modified UCH-L1 in mammalian cells, such as their protein interactions or detergent insolubility (i.e. the amount of a protein in the insoluble fraction), are poorly understood.

In this study, we analyzed the molecular properties of carbonyl-modified UCH-L1 and UCH-L1^{I93M} and elucidated novel properties of UCH-L1 variants, including protein interactions. We show that carbonyl-modified UCH-L1 and UCH-L1^{I93M} share common properties. Our findings provide novel insights into understanding the mechanisms underlying the toxic gain of function by mutant UCH-L1 and suggest that oxidative stress and subsequent protein interactions of carbonyl-modified UCH-L1 constitute one of the causes of sporadic PD. We also discuss the possible involvement of oxidative modifications of UCH-L1 in other neurodegenerative diseases.

RESULTS

Disease-associated mutants including UCH-L1^{I93M} display aberrant insolubility

Aberrantly increased insolubility compared with wild-type protein is a common biochemical feature of several mutant proteins associated with neurodegenerative diseases: for example, mutant α-synuclein associated with familial PD (15), mutant SOD1 associated with familial amyotrophic lateral sclerosis (ALS) (16,17) and mutant tau associated with frontotemporal dementia and parkinsonism linked to chromosome 17 (18). Although we have previously shown that the insolubility of UCH-L1 in the UCH-L1^{I93M}-transgenic mouse brain is increased compared with that in wild-type mouse (2), the insolubility of UCH-L1^{I93M} itself has been unclear. We observed that pathogenic α-synuclein and SOD1 mutant proteins exhibit increased detergent insolubility in mammalian cells compared with wild-type proteins (Fig. 1A and B). The insolubility of UCH-L1^{I93M} was examined under the same experimental conditions, in which the causative mutants are distinguishable from wild-type proteins. We found that, in dopaminergic SH-SY5Y cells, the protein level of UCH-L1^{I93M} in the insoluble fraction was markedly higher than the levels of UCH-L1^{WT}, UCH-L1^{S18Y}, UCH-L1^{D30K}, which lacks hydrolase activity and binding affinity for ubiquitin (8), and UCH-L1^{C90S}, which lacks hydrolase activity but maintains binding affinity for ubiquitin (8) (Fig. 1C). There was no notable difference among the soluble protein levels (Fig. 1C). The formation of high molecular weight aggregates, which is also a common feature of several mutants, was observed almost exclusively in the insoluble fraction with UCH-L1^{I93M} (Fig. 1C), consistent with the report that UCH-L1^{I93M} produced more aggresomes than UCH-L1^{WT} (19). Increased insolubility of UCH-L1^{I93M} and UCH-L1$^{S18Y/I93M}$ and an increase in the amounts of aggregates specific for these proteins were observed in COS-7 cells (Fig. 1D; Supplementary Material, Fig. S1A), which express very low levels of endogenous UCH-L1. These results demonstrate that UCH-L1^{I93M} shares common features with several mutant proteins linked to neurodegenerative diseases, thus, further supporting the idea that the I93M mutation in UCH-L1 is a causative mutation for PD. Our results also suggest that the insolubility of UCH-L1 is independent of monoubiquitin-binding.

UCH-L1^{I93M} abnormally interacts with multiple proteins

Although increased insolubility is a common characteristic of several mutant proteins associated with neurodegenerative diseases, and this may play a role in the neurotoxicity of the mutant proteins, accumulating evidence suggests that a soluble mutant is the main cause of neurodegeneration (20,21). Studies of dominantly inherited neurodegenerative disease-linked mutants strongly suggest that abnormal physical interactions of the mutant proteins with other proteins constitute a cause of disease (22–26). Hence, we next examined the effect of the I93M mutation on the protein interactions of soluble UCH-L1 using a co-immunoprecipitation (coIP) assay. Silver staining of immunoprecipitant revealed that UCH-L1^{WT} interacts with multiple proteins over 30 kDa (Fig. 1E). We found that the amount of each protein interacting with UCH-L1^{I93M} is mostly higher than the amount interacting with UCH-L1^{WT} or other UCH-L1 variants (Fig. 1F; Supplementary Material, Fig. S1B). Monoubiquitin binding of UCH-L1^{I93M} was decreased compared with that of UCH-L1^{WT} (Fig. 1G), consistent with the decreased hydrolase activity of UCH-L1^{I93M} (1,9). However, the cellular monoubiquitin level in cells expressing UCH-L1^{I93M} was not changed compared with that in cells expressing UCH-L1^{WT} (Fig. 1G). Since UCH-L1^{I93M}-associated PD is presumably caused by an acquired toxicity, the toxic function of UCH-L1^{I93M} may not be mainly mediated by a decreased interaction with monoubiquitin, but rather by aberrantly elevated interactions with multiple other proteins.

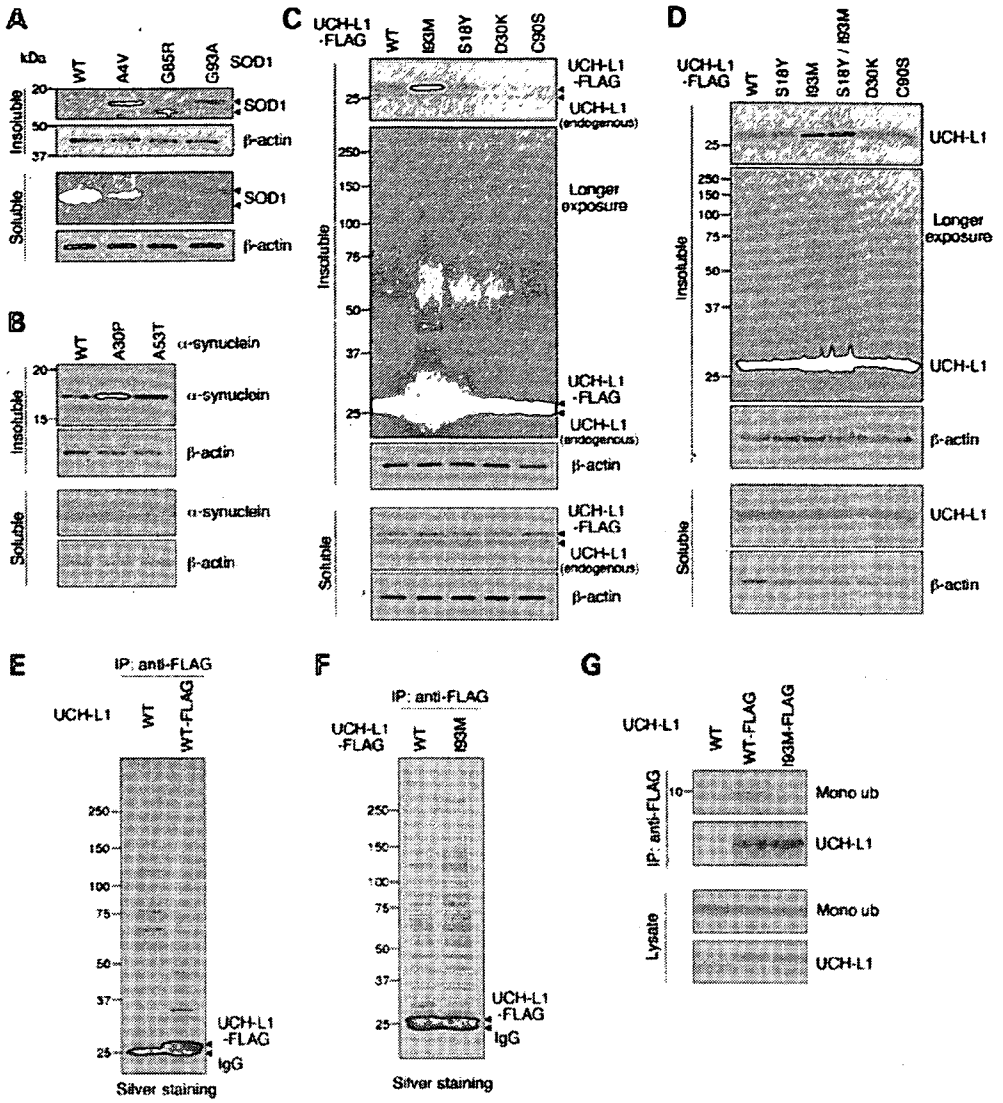

Figure 1. Aberrant biochemical properties of mutant I93M UCH-L1. [(**A**)–(**D**)] SH-SY5Y (A) and (C), Neuro2a (B) and COS-7 cells (D) were transfected with the indicated constructs. Forty-eight hours after transfection, soluble and insoluble fractions were prepared and analyzed by immunoblotting. [(**E**)–(**G**)] COS-7 cells were transfected with the indicated constructs. Cell lysates were immunoprecipitated using anti-FLAG antibody and analyzed by silver staining [(E) and (F)] or by immunoblotting (G). In the presence of FLAG-tagged UCH-L1, UCH-L1-interacting proteins were co-immunoprecipitated with UCH-L1 [(E), lane 2], whereas in the absence of FLAG-tagged UCH-L1, proteins were non-specifically precipitated with anti-FLAG beads [(E), lane 1]. Mono ub, monoubiquitin (G).

Carbonyl-modified UCH-L1 exhibits aberrant properties common to UCH-L1^{I93M}

In the brains of sporadic PD patients, UCH-L1 is a major target of carbonyl formation (12). Carbonyl groups can be introduced into proteins *in vivo* mainly by reactions with 2-alkenals, 4-hydroxy-2-alkenals (HAE) or ketoaldehydes, which are endogenous aldehydic products formed by lipid peroxidation or glycooxidation (27,28). Protein carbonyls can also be produced by metal-catalyzed reactions with H_2O_2 *in vitro* (28,29). To analyze the biochemical properties of carbonyl-modified UCH-L1, we used several carbonyl compounds or H_2O_2 to modify UCH-L1. We have previously reported that UCH-L1 is modified by 4-hydroxy-2-nonenal (HNE) *in vitro* (9). In COS-7 cells transfected with UCH-L1^{WT}, UCH-L1 was modified by physiological concentrations of HNE (10–100 μM) (9) or 4-hydroxy-2-hexenal (HHE) in a dose-dependent manner (Fig. 2A and B; Supplementary Material, Fig. S1C). Carbonyl modification of UCH-L1 was also detected when cells were treated with 100 μM 2-propenal (Fig. 2A), but not with 100 or 500 μM methylglyoxal, 100 or 500 μM malondialdehyde, both of which are ketoaldehydes, or 0.1 or 1 mM H_2O_2 (data not shown). Thus, carbonyl-modified UCH-L1 can be produced by reactions with HAE or 2-alkenals in mammalian cells.

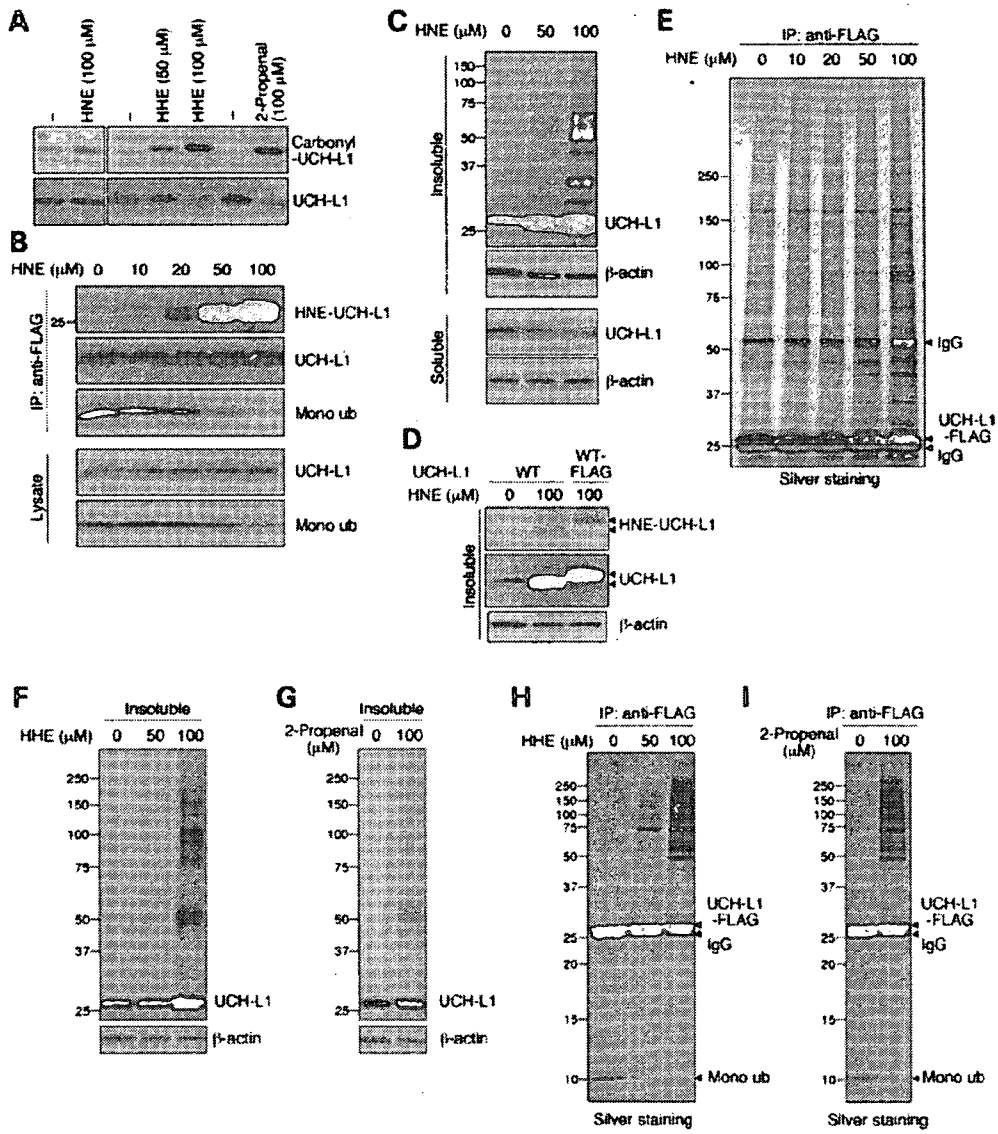

Figure 2. Abnormal biochemical properties of carbonyl-modified UCH-L1. **(A)** COS-7 cells transfected with FLAG-tagged UCH-L1^{WT} were treated with or without the indicated concentrations of carbonyl compounds for 90 min, and immunoprecipitation was performed using anti-FLAG antibody. To detect carbonyl-modified UCH-L1, immunoprecipitants were derivatized with DNPH and immunoblotted using anti-DNP or anti-UCH-L1 antibodies. [**(B)**, **(E)**, **(H)** and **(I)**] COS-7 cells transfected with FLAG-tagged UCH-L1^{WT} were treated with the indicated concentrations of HNE [(B) and (E)], HHE (H) or 2-propenal (I) for 90 min, and immunoprecipitation was performed using anti-FLAG antibody. Immunoprecipitants were analyzed by immunoblotting or by silver staining. [**(C)**, **(F)** and **(G)**] COS-7 cells transfected with FLAG-tagged UCH-L1^{WT} were treated with the indicated concentrations of HNE (C), HHE (F) or 2-propenal (G). Soluble and insoluble fractions were analyzed by immunoblotting. **(D)** COS-7 cells transfected with the indicated constructs were treated with or without HNE, and insoluble fractions were prepared. Immunoblotting shows that the insoluble UCH-L1 that is accumulated upon HNE treatment is modified by HNE.

Interestingly, carbonyl-modified UCH-L1 and UCH-L1^{I93M} exhibit common biochemical properties: ubiquitin binding of HNE-modified UCH-L1 was decreased (Fig. 2B), and both the insolubility of HNE-modified UCH-L1 and the interactions of HNE-modified UCH-L1 with proteins over 30 kDa were increased, compared with those of UCH-L1^{WT} (Fig. 2C–E). HHE and 2-propenal had similar effects to HNE (Fig. 2F–I). Treatment of cells with 100 μM H_2O_2, methylglyoxal or malondialdehyde had no effect on the insolubility of UCH-L1 or the interactions of UCH-L1 with other proteins (data not shown). Consistent with the report that UCH-L1 is a major target of carbonyl formation in the brains of sporadic PD patients (12), UCH-L1 is a major target of carbonyl modification in cells treated with HNE (Fig. 3A). We used the EF1 promoter to yield abundant expression of UCH-L1 in this experiment, since the amount of UCH-L1 is 1–5% of

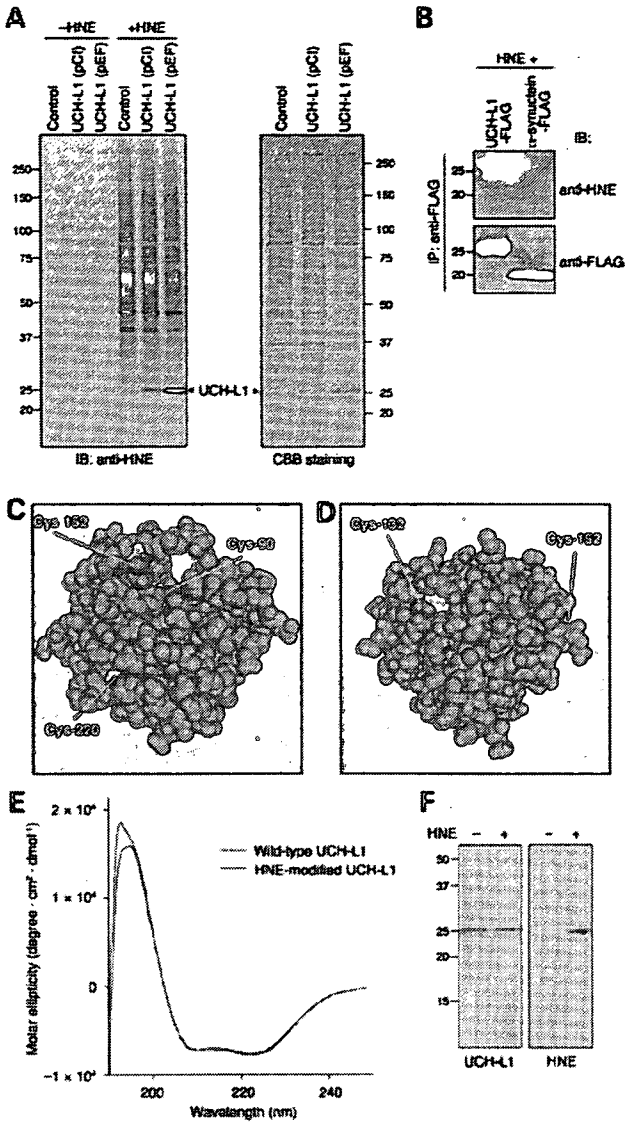

Figure 3. Susceptibility of UCH-L1 to HNE modification and structural properties of UCH-L1 variants. **(A)** COS-7 cells transfected with the indicated constructs were treated with or without 100 μM HNE and analyzed by immunoblotting and CBB staining. **(B)** COS-7 cells transfected with the indicated constructs were treated with 100 μM of HNE, and immunoprecipitation was performed using anti-FLAG antibody. Immunoprecipitants were analyzed by immunoblotting. [**(C)** and **(D)**] Structural model for human UCH-L1. Cys-90, Cys-152 and Cys-220 sidechains are shown in magenta, and backbones are shown in blue (C), using Cn3D software (version 4.1) and NCBI's structural model (mmdbId:38174). Cys-132 and Cys-152 sidechains are shown in magenta, and backbones are shown in blue (D). **(E)** CD spectra (mean residue ellipticity) for recombinant human UCH-L1 proteins. Wild-type UCH-L1 is shown in red and HNE-modified UCH-L1 in blue. **(F)** HNE modification of the recombinant UCH-L1 used in (E) was analyzed by immunoblotting. Modification of UCH-L1 by HNE was detected.

soluble protein in the brain (5). These results suggest that the carbonyl-modified UCH-L1 in sporadic PD brains functions as a causative factor for disease in a similar manner to UCH-L1^{I93M}.

Cys-90 and Cys-152 of UCH-L1 are targets for HAE modification

The appearance of HNE-modified proteins in nigral neurons has been shown to be associated with sporadic PD (30,31). Therefore, we next determined the HNE-modified amino acid residues of UCH-L1 that regulate its insolubility and protein interactions. HNE can form covalent cross-links with cysteine, lysine and histidine residues in proteins (28). To test the specificity of HNE modification in mammalian cells, we used cells transfected with α-synuclein, which contains no cysteine residues. HNE modification of α-synuclein was not detected when cells were treated with 100 μM HNE (Fig. 3B). These results suggest that among the amino acid residues of UCH-L1, cysteine residues are the primary target for HAE. We speculated that Cys-90 is accessible to HAE, since it is a ubiquitin-binding residue. Using the three-dimensional structure of human UCH-L1 (32), we observed that not only Cys-90 but also Cys-132 and Cys-152 are located on the surface of the protein (Fig. 3C and D). Thus, we tested the insolubility and protein interactions using C90S, C132S and C152S UCH-L1 mutant proteins. We also used C220S UCH-L1 as a control. We found that the C152S mutant bound to monoubiquitin in both HNE-treated cells and untreated cells (Fig. 4A). UCH-L1^{C90S} did not exhibit notably increased insolubility upon HNE-treatment compared with UCH-L1^{WT} (1.3-fold increase in UCH-L1^{C90S}, 2.5-fold increase in UCH-L1^{WT}) (Fig. 4B). The amount of proteins over 30 kDa interacting with UCH-L1^{C90S} was markedly lower than that interacting with UCH-L1^{WT} when cells were treated with HNE (Fig. 4C). Similar results were obtained when cells were treated with HHE (Fig. 4E and F; Supplementary Material, Fig. S1D). Mutations at Cys-132 and Cys-220 had no effect on protein insolubility or interactions (Fig. 4A–C). Consistent with these results, HNE modification of C90S and C152S mutants was decreased compared with that of UCH-L1^{WT} when cells were treated with HNE (~40 and 60% decrease, respectively) (Fig. 4D). These results indicate that HAE modification of UCH-L1 at Cys-90 increases the insolubility and interactions of UCH-L1, and modification of Cys-152 reduces monoubiquitin binding. The level of HNE modification of UCH-L1^{I93M} upon HNE-treatment was markedly lower than that of UCH-L1^{WT} (Fig. 4G). Since the location of Cys-90 is close to Ile-93 (Supplementary Material, Fig. S2), it is possible that the I93M mutation and HAE modification at Cys-90 cause similar structural changes in UCH-L1.

HNE modification causes structural changes in UCH-L1

To address the structural changes in carbonyl-modified UCH-L1, we used CD spectroscopy to estimate the secondary structure. We have previously shown that, compared with UCH-L1^{WT}, the I93M mutant displays lower ellipticity around 195 nm, suggesting a decreased α-helix content, and an increase in the content of β-sheet (9,10). Relative to wild-type protein, HNE-modified UCH-L1 also displayed a lower peak around 190–195 nm (Fig. 3E and F). The relative proportions of α-helix, β-sheet and other secondary structural features in these proteins were estimated from mean residue ellipticity data. HNE-modified UCH-L1 also exhibited

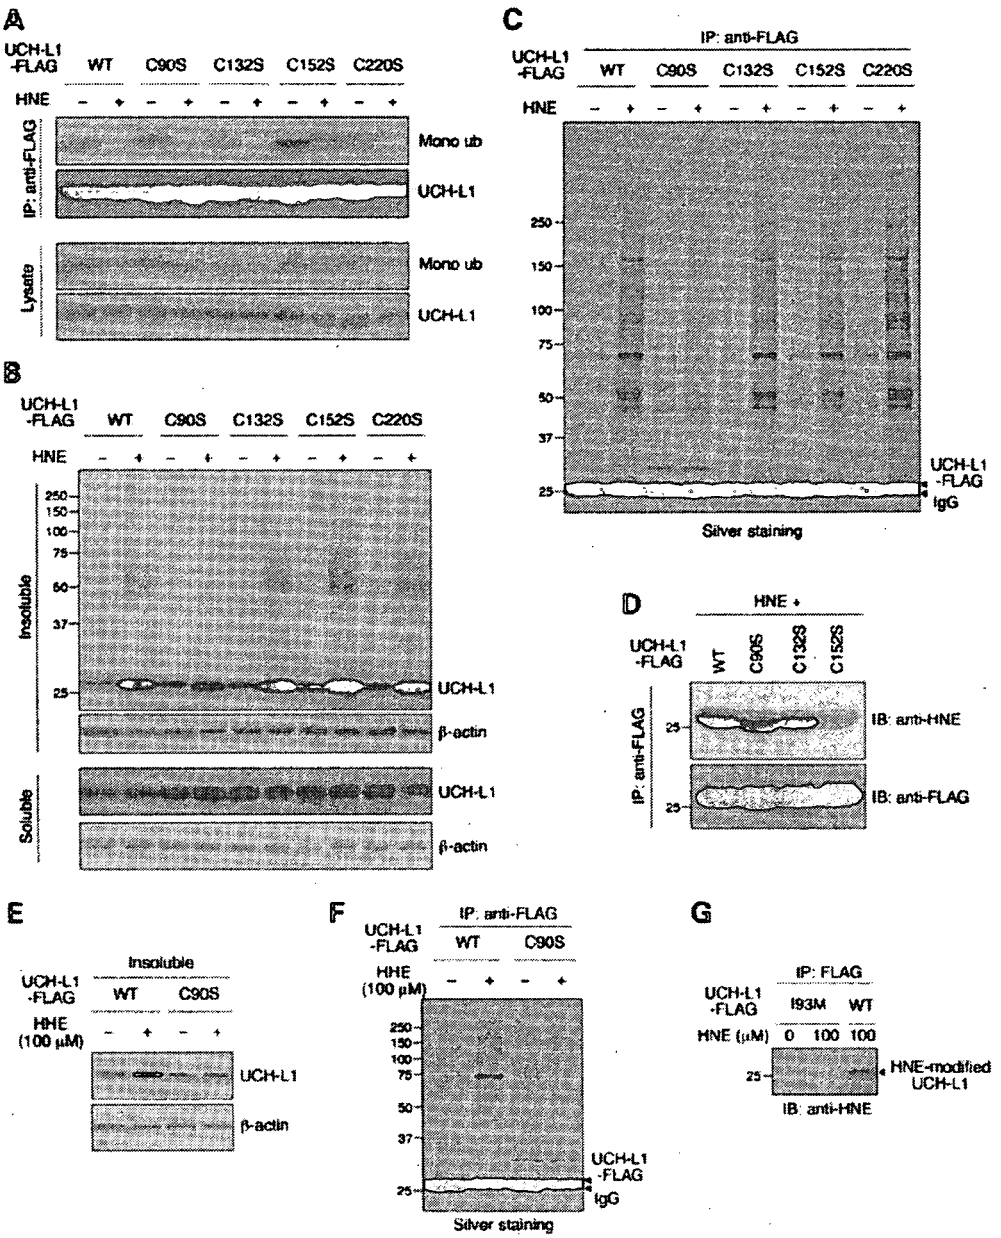

Figure 4. Cysteine residues of UCH-L1 modified by HAE. [(**A**), (**C**), (**D**), (**F**) and (**G**)] COS-7 cells transfected with the indicated constructs were treated with or without 100 μM HNE or HHE. Immunoprecipitation was performed using anti-FLAG antibody, and immunoprecipitants were analyzed by immunoblotting or by silver staining. [(**B**) and (**E**)] COS-7 cells transfected with the indicated constructs were treated with or without 100 μM HNE or HHE. Soluble and insoluble fractions were analyzed by immunoblotting.

decreased α-helix content, and an increase in the content of β-sheet compared with UCH-L1^{WT} (42.9% α-helix, 20.9% β-sheet, 20.6% β-turn and 15.7% random for UCH-L1^{WT}, and 34.0% α-helix, 27.3% β-sheet, 22.3% β-turn and 16.4% random for HNE-modified UCH-L1). These results suggest that UCH-L1^{I93M} and carbonyl-modified UCH-L1 adopt a similar aberrant structure.

The ALS-linked mutation in SOD1 increases its hydrophobicity, which may promote aberrant interactions of SOD1 with other cellular constituents (33). However, the interactions of UCH-L1^{I93M} or HNE-modified UCH-L1 with hydrophobic beads were not altered relative to those of UCH-L1^{WT} (data not shown), indicating that the I93M mutation and HNE modification of UCH-L1 do not increase its hydrophobicity. Considering the fact that unnatural β-sheet proteins readily become insoluble or form further β-hydrogen-bonding with other β-strands they encounter (34), our results suggest that the increased insolubility and protein interactions of abnormal UCH-L1 are due to the increased β-sheet content of UCH-L1.
