Intramembrane proteolysis by presenilin-dependent γ -secretase produces the Notch intracellular cytoplasmic domain (NICD) and Alzheimer disease-associated amyloid- β . Here, we show that upon Notch signaling the intracellular domain of Notch-1 is cleaved into two distinct types of NICD species due to diversity in the site of S3 cleavage. Consistent with the N-end rule, the S3-V cleavage produces stable NICD with Val at the N terminus, whereas the S3-S/S3-L cleavage generates unstable NICD with Ser/Leu at the N terminus. Moreover, intracellular Notch signal transmission with unstable NICDs is much weaker than that with stable NICD. Importantly, the extent of endocytosis in target cells affects the relative production ratio of the two types of NICD, which changes in parallel with Notch signaling. Surprisingly, substantial amounts of unstable NICD species are generated from the Val \rightarrow Gly and the Lys \rightarrow Arg mutants, which have been reported to decrease S3 cleavage efficiency in cultured cells. Thus, we suggest that the existence of two distinct types of NICD points to a novel aspect of the intracellular signaling and that changes in the precision of S3 cleavage play an important role in the process of conversion from extracellular to intracellular Notch signaling.

Presenilin (PS)-dependent γ -secretase (PS/ γ -secretase) mediates the degradation of transmembrane domains (TMs) in many type 1 receptors, including Notch and β -amyloid protein precursor (β APP) (18, 52). Degradation of these receptors is characterized by sequential endoproteolysis: following shedding by cleavage in the extracellular juxtamembrane region, the receptors undergo PS-dependent intramembrane proteolysis, releasing amyloid- β ($A\beta$)-like peptides and intracellular cytoplasmic domains (ICDs) (5, 14). At least in the cases of β APP, Notch, and CD44, cleavages of the C termini of $A\beta$ -like peptides and of the N termini of ICDs in the TM are distinct. This process of cleavage at two sites is known as “dual cleavage” (33). The process of $A\beta$ generation has been intensively studied, and it is suggested that $A\beta$ is released by a series of sequential cleavages followed by the ICD generation (25, 36, 53). An unusual characteristic of this intramembrane proteolysis is that some of the cleavage sites can vary (42). The precision of cleavage can therefore be defined as the ratio of the cleavage at each site. For example, PS-dependent cleavage of β APP at the γ site, which is associated with Alzheimer disease

(AD), occurs mainly at residue 40 (γ 40), producing $A\beta$ 40, and at residue 42 (γ 42), producing $A\beta$ 42. A small increase in the proportion of γ 42 to γ 40 cleavage is consistently observed in many familial AD (FAD)-associated PS or β APP mutants (42), but it is unclear whether such changes in the precision of PS-dependent intramembrane proteolysis have any biological effects.

Notch signaling, which is essential for development, is a type of local-cell signaling that participates in neurodegeneration and tumorigenesis (1). The canonical Notch pathway is mediated by the regulated intramembrane proteolysis pathway, in which Notch receptors undergo ligand-dependent sequential endoproteolysis via a series of enzymes, including PS/ γ -secretase (8). The Notch-1 ICD (NICD), which is produced by PS/ γ -secretase-mediated cleavage at site 3 (S3), translocates to the nucleus and participates in transactivation of target genes (40). Elimination of PS function results in the Notch phenotype, which includes disruption of segmentation during the development of many kinds of animals, demonstrating the importance of NICD generation (41).

The intensity of Notch signaling is crucial for cell fate decisions. For example, Notch haplo-insufficiency causes the “notched-wing” phenotype in *Drosophila* (9). Reduced Notch activity favors the $\gamma\delta$ T-cell fate over the $\alpha\beta$ T-cell fate, whereas a constitutively activated form of Notch produces a reciprocal phenotype (48). The endocytosis of Notch and its ligands plays a key role in the regulation of the signaling intensity (40), but the biochemical aspects regulating this process have not been well studied. N-terminal amino acid se-

quencing revealed that S3 in mouse Notch-1 lies between Gly1743 and Val1744 (murine Notch-1 numbering) (39). Whether the site of S3 cleavage can vary has not been examined previously.

In this study, we found that there is diversity in the site of S3 cleavage, resulting in the production of two types of NICD with apparently distinct stability and ability to transmit Notch signaling in cultured cells. Our results suggest that the precision of PS/ γ -secretase-mediated cleavage is important for determining the intensity of Notch signaling.

MATERIALS AND METHODS

Antibodies. To generate affinity-purified polyclonal N-terminal capping antibodies to NICD-S (anti-NT-S), rabbits were immunized with a synthetic peptide (SRKRR) corresponding to the N terminus of NICD-S(+3). We also prepared two kinds of affinity columns in which the N-terminal peptide of NICD-V (VLLSRKRR) or NICD-S (SRKRR) was conjugated to Sepharose 4B (Amersham). We isolated the fraction of the anti-NT-S antiserum that bound to the NICD-S(+3) column but not the NICD-V column (32). Anti-NT-L antiserum was raised against a synthetic peptide (LLSRKRR) corresponding to the N terminus of NICD-L(+1) and then purified by affinity chromatography on Sepharose 4B conjugated to the N-terminal peptide of NICD-L (LLSRKRR), followed by a second step of affinity chromatography on Sepharose 4B conjugated to the NICD-S peptide (SRKRR). Other antibodies were purchased from commercial sources as follows: anti-NT-V (V1744 antibody) from Cell Signaling; antincastrin and antibody mN1A against Notch-1 from Sigma-Aldrich; antibody H114 against Jagged-1 and antitubulin from Santa Cruz Biotechnology; anti-early endosome antigen 1 and anti-GM130 from BD Transduction Laboratories; antibody 12CA5 against the HA epitope from Roche Diagnostics, Inc.; antibody 9E10 against the myc epitope from Zymed; and anti-Na-K ATPase from Upstate Biotechnology.

cDNA constructs. The cDNA encoding the mouse Notch-1 variant NEXT was previously described (33). NEXTAC was generated by PCR-based mutagenesis using the QuikChange-II kit (Stratagene) with NEXT cDNA as a template. The mutant versions of NEXT and NEXTAC were generated using the same kit. To generate expression constructs for polypeptides NICD-V, NICD-L (+1), and NICD-S (+3), cDNAs encoding Val, Leu(+1), and Ser(+3) as the N termini were subcloned into the pASK-IBA6 vector (IBA). *HES-1*-luc (a kind gift from Alain Israel) (16) and pGa981-6 (a kind gift from Georg W. Bornkamm) (21) were used as described. For more sensitive detection of *HES-1* promoter transactivation, we newly generated a *hairy* and *enhancer of split-Y* (*HES-Y*) construct containing four sequential RBP- τ binding sites in the *HES-1* promoter region.

Cell culture. We generated HEK293 cells expressing PS1 R278I (a kind gift from M. Nishimura) (27) or PS1 G384A (a kind gift from H. Steiner) (44). HEK293 cells expressing either wild-type (wt) or mutants of PS1 were previously described (31). These cells were transfected with wt, mutant NEXT, or mutant NEXTAC. HeLa cells expressing Dyn-1 K44A (a kind gift from S. Schmid) were used as described and stably transfected with NEXT or NEXTAC. CHO(r) cells (a gift from S. Shirahata) (29) were stably transfected with mouse Notch-1 or Jagged-1.

Cell-free Notch-1 cleavage assay. To obtain crude membrane fractions (CMFs), cells were homogenized in buffer (0.25 M sucrose and 10 mM HEPES, pH 7.4) containing a protease inhibitor cocktail (Roche), followed by centrifugation at $1,000 \times g$ for 5 min. The postnuclear supernatant was further centrifuged at $100,000 \times g$ for 30 min, and the resulting pellet was collected. This CMF was resuspended in 150 mM sodium citrate buffer (pH 6.4) containing a 4 \times concentration of protease inhibitor cocktail (Sigma-Aldrich) and 5 mM 1,10-phenanthroline (Sigma-Aldrich), incubated for 20 min at 37°C, and then centrifuged at $100,000 \times g$ for 30 min (11).

Pulse-chase experiments. Pulse-chase experiments were performed as described previously (11, 30, 31, 33, 34).

Immunoprecipitation/MALDI-TOF MS. Immunoprecipitation and matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry (MALDI-TOF MS) analysis was carried out as described previously (11, 31, 33). The heights of the MS peaks and molecular weights were calibrated using angiotensin and bovine insulin β -chain as standards (Sigma-Aldrich).

Immunoprecipitation-immunoblotting and immunoprecipitation-autoradiography. Metabolically labeled or unlabeled lysates were lysed in radioimmunoprecipitation assay buffer (1% Triton X-100, 0.5% sodium deoxycholate, and 0.1% sodium dodecyl sulfate [SDS]) containing a protease inhibitor mix (Sigma-

Aldrich). The cell lysates were centrifuged at $10,000 \times g$ for 15 min, and the supernatant fractions were immunoprecipitated as indicated. Following 8% Tris-glycine (Tefco) or 10 to 20% Tris-Tricine (Invitrogen) SDS-polyacrylamide gel electrophoresis (SDS-PAGE), the gels were either transferred to a polyvinylidene difluoride membrane and probed with the indicated antibodies or dried and analyzed by autoradiography. To quantitatively measure the levels of NICD species in cultured cells, several doses of each NICD polypeptide were separated together with samples by SDS-PAGE and analyzed by immunoblotting with the corresponding N-terminal capping antibody. The chemiluminescence intensities were measured using an LAS3000 scanner, followed by analysis with Multi Gauge Ver3.0 software (Fuji Film). Biotinylated transferrin was semiquantitatively measured by chemiluminescence using the scanner, followed by analysis with the software.

Cell-cell association assay. For the detection of de novo NICD species, CHO(r) cells stably expressing Notch-1 were grown to confluence in 150-mm dishes (2×10^7 cells per dish) in triplicate. Next, 3×10^7 CHO(r) cells stably expressing Jagged-1 were spread over the Notch-1-expressing cells. After 8 h of coculture, the cells were collected. For the reporter assay, the procedure was the same, although it was carried out in a 12-well plate and the number of cells was reduced accordingly.

cDNA transfection and reporter assay. To examine the intensity of Notch signaling, we used a dual luciferase reporter assay system (Promega) as described by the manufacturer (31). Briefly, cells expressing Notch-1 or its derivatives in a 12-well plate were transiently transfected with 125 ng of *HES-Y* or pGa981-6 and 1.25 ng of the control *Renilla* luciferase reporter plasmid pRL-TK. The reporter assay was performed on the next day. Dyn-1 K44A expression was induced with various concentrations of tetracycline 24 h prior to transfection with *HES-Y*. Cell-cell association was performed 24 h after transfection with *HES-Y*.

Preparation of nuclear extract from mouse tissues. A nuclear complex co-IP kit (Active Motif) was used to obtain nuclear extracts from C57BL/6 (Japan SLC) mouse tissues. Homogenized adult mouse brain or fetal mouse tissues without internal organs (embryonic day 12) were treated according to the manufacturer's instructions. Subsequently, the nuclear extracts were diluted using the immunoprecipitation buffer included in the kit, precleared three times with protein G- or protein A-Sepharose, and immunoprecipitated according to the manufacturer's instructions.

Purification of polypeptides. NICD-V, NICD-L(+1), and NICD-S(+3) polypeptides fused with *strept-tag-II* followed by an N-terminal factor Xa cleavage site were obtained by transforming *Escherichia coli* (BL21) with pASK-IBA6 (IBA) encoding each polypeptide. Briefly, after the expression was induced, the cells were collected by centrifugation at $4,500 \times g$ for 12 min, resuspended in ice-cold TSE buffer (10 mM Tris-HCl [pH 7.4], 20% sucrose, and 2.5 mM Na-EDTA), and then incubated on ice for 10 min. The cells were again collected by centrifugation, resuspended in ice-cold water, incubated for 10 min, briefly sonicated, and sedimented by centrifugation at $14,000 \times g$ for 15 min (osmotic shock fractionation). The supernatant was passed through a Strep-Tactin Sepharose column (IBA). Bound polypeptides were eluted with phosphate-buffered saline containing 2.5 mM desthiobiotin. Eluted polypeptides were treated with factor Xa (Sigma-Aldrich), and the solution was passed through the column again to remove uncleaved polypeptide (34). The purity of the polypeptides was confirmed by 6% Tris-glycine SDS-PAGE, followed by staining with Coomassie brilliant blue.

Loading of polypeptides. The polypeptides obtained as described above were loaded into cells using Chariot protein transfection reagent (Active Motif) according to the manufacturer's instructions. Briefly, cells were grown and transfected with reporter genes in a 12-well plate. The cells were then loaded with 5 μ g of each polypeptide or bovine serum albumin (BSA) along with 0.5 μ g of β -galactosidase, using 15 μ l of Chariot reagent per well. Finally, the cells were stained for β -galactosidase or used for the reporter assay.

In vitro degradation assay. NICD polypeptides (0.2 μ g) were mixed with 60 μ l of fresh rabbit reticulocyte lysate (Promega) and incubated at 37°C. Clastolactacystin (10 μ M), MG262 (100 nM), and 4-hydroxy-5-iodo-3-nitrophenylacetyl-Leu-Leu-leucinal-vinyl sulfone (NLVS) (10 μ M) were added to inhibit the action of the proteasome.

Transferrin uptake assay. To estimate the rate of endocytosis, the levels of internalized and surface-bound biotinylated-transferrin were measured as described previously (11).

Subcellular fractionation. Linear gradients of 2.5% to 25% iodixanol (Optiprep; Axis-Shield) were prepared, and fractionation was performed as previously described (11).

Statistical analysis. Experiments were performed at least three times unless otherwise indicated. Representative results are shown for cell-free immunoprecipitation/MALDI-TOF MS, immunoblotting, immunoprecipitation-autoradiog-

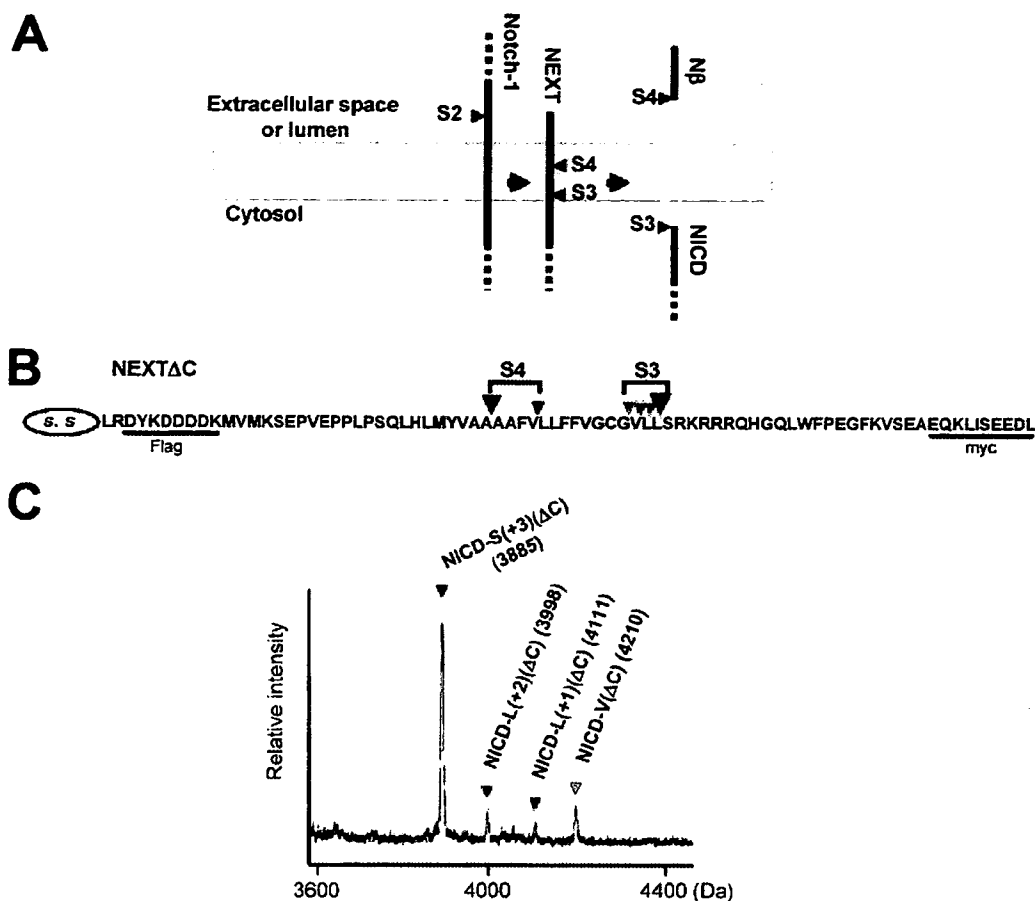

FIG. 1. MALDI-TOF MS analysis of NICD(Δ C) produced by the cell-free Notch-1 cleavage assay. (A) Schematic representation of sequential endoproteolysis of Notch-1. S2 to S4 and the gray area represent the proteolytic sites and the putative TM, respectively. (B) Schematic representation of the NEXT Δ C construct used in the cell-free Notch-1 cleavage assay. Colored inverted triangles show the S3 and S4 proteolytic sites. S.S., signal sequence. (C) MS spectrum of de novo NICD(Δ C) generated in the cell-free assay. CMF was derived from K293 cells stably expressing NEXT Δ C. The molecular mass of each species is indicated. To inhibit degradation by proteases other than aspartyl proteases, BSA and a mixture of metallo-, serine, and cysteine protease inhibitors were added to the cell-free assay buffer. Colored inverted triangles indicate the NICD(Δ C) species produced by cleavage at the sites shown in panel B.

raphy, and immunocytochemistry. The statistical significance of differences was determined by Student's *t* test.

RESULTS

A cell-free Notch-1 cleavage assay indicates diversity in the site of S3 cleavage. The cleavage of the Notch-1 TM occurs at least at two sites, one at S3, which determines the N terminus of intracellularly liberated NICD (39), and the other at S4, which determines the C terminus of extracellularly secreted N β (Fig. 1A) (31, 33). We first examined the diversity of the S3 cleavage site. We constructed NEXT Δ C, a mouse Notch-1 derivative that lacks the majority of its extracellular and intracellular domains (Fig. 1B), and we established a cell-free Notch-1 cleavage assay using the CMF from cells stably expressing this construct (11). The de novo-generated NICD(Δ C) was immunoprecipitated with anti-myc antibodies and then analyzed by MALDI-TOF MS (Fig. 1C). Strikingly, proteolysis at S3 did not occur at a unique site but rather occurred at multiple sites, as indicated by the presence of multiple sizes of NICD(Δ C) (see Table S1 in the supplemental

material). Specifically, proteolysis at S3 occurred at the following sites: S3-L(+1), between Val1744 and Leu1745; S3-L(+2), between Leu1745 and Leu1746; S3-S(+3), between Leu1746 and Ser1747; and the previously reported S3-V, between Gly1743 and Val1744 (39) (Fig. 1B; see Fig. S1A in the supplemental material). Unexpectedly, the highest peak was for NICD-S(+3)(Δ C) rather than NICD-V(Δ C) (Fig. 1C), suggesting that S3-S(+3) is the major site of S3 cleavage under these assay conditions. Addition of the PS/ γ -secretase inhibitors eliminated the cleavage at both S3-V and S3-S(+3) (see Fig. S1B in the supplemental material). Moreover, we did not observe generation of these shorter NICD(Δ C) species from the longer NICD(Δ C) (see Fig. S1C in the supplemental material). Therefore, the results are consistent with the possibility that all the fragments are produced by PS-dependent S3 cleavage in the Notch-1 TM.

Diversity in the site of S3 cleavage in living cells. To identify the N terminus of NICD molecules in vivo, we prepared two N-terminal capping antibodies, anti-NT-V (anti-V1744) and anti-NT-S (32), and corresponding recombinant NICD species

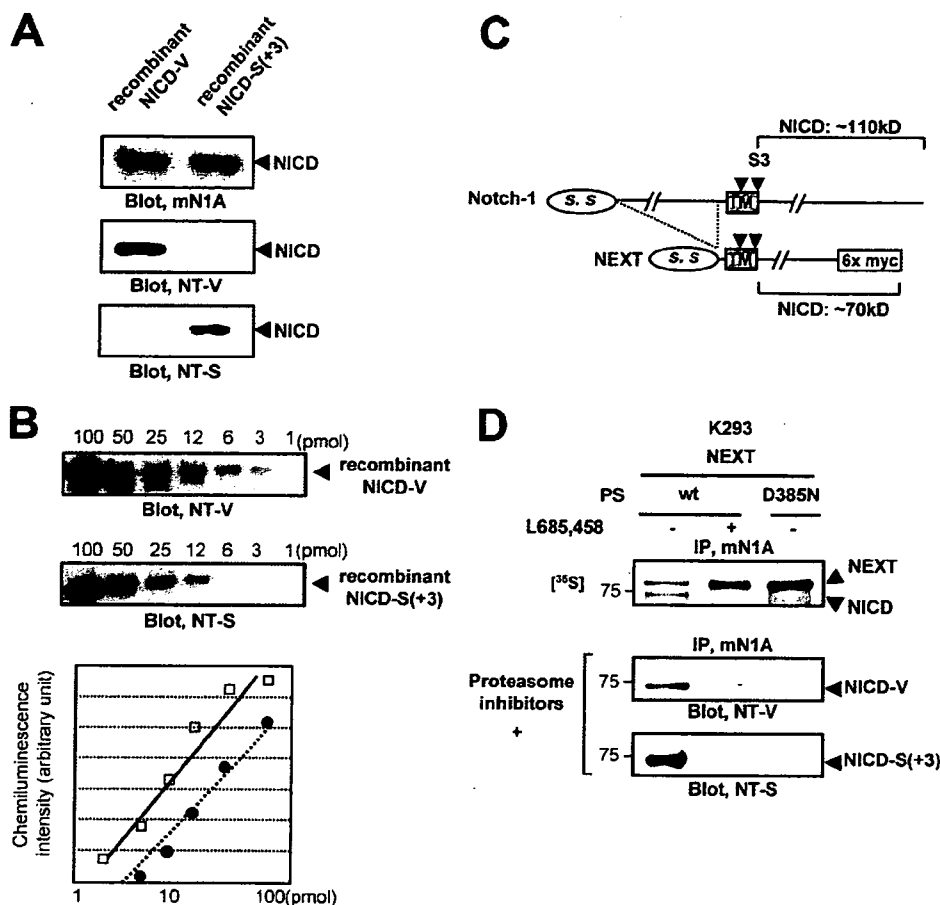

FIG. 2. Characterization of capping antibodies to the N terminus of NICD and detection of distinct NICD species in cultured cells. (A) Specificities of the anti-NT-V and the anti-NT-S antibodies. Immunoblotting with antibody mN1A confirmed that equal amounts of the polypeptides were loaded in each lane (upper panel). (B) Affinities of the anti-NT-V and anti-NT-S antibodies. The indicated amounts of NICD-V or NICD-S(+3) were separated by SDS-PAGE and analyzed by immunoblotting with the anti-NT-V or anti-NT-S antibody, respectively. The graph shows the chemiluminescence intensity versus the concentration of NICD-V (squares) or NICD-S(+3) (circles). Each antibody detected the respective polypeptide in a dose-dependent manner. (C) Schematic representation of Notch-1 and NEXT constructs. The C-terminal portion of the NEXT construct is replaced by myc₆, while full-length Notch-1 has no modification. Note that the molecular mass of NICD generated from NEXT-myc₆ is ~70 kDa, while that of NICD generated from unmodified Notch-1 is ~110 kDa. (D) Generation of NICD-V and NICD-S(+3) in cultured cells. Proteasome inhibitors lactacystin (10 μ M), MG262 (100 nM), and NLVS (10 μ M) were added to the medium 12 h prior to cell collection.

with distinct N termini (Fig. 2A; see Fig. S2A in the supplemental material). We found that (i) the anti-NT-V antibody specifically recognizes recombinant NICD-V but not NICD-S(+3) (34) (Fig. 2A, middle panel; see Fig. S2B in the supplemental material), whereas the anti-NT-S antibody has the opposite specificity (Fig. 2A; lower panel, see also Fig. S2B in the supplemental material), and (ii) these antibodies can be used to determine the relative amounts of NICD-V and NICD-S(+3) generated, that is, the extents of S3-V and S3-S(+3) cleavage, respectively (Fig. 2B).

Using these capping antibodies, we examined the diversity in the site of S3 cleavage in living cells. The Notch extracellular truncation (NEXT) (Fig. 2C), which lacks the majority of the extracellular domain of Notch-1, undergoes constitutive ligand-independent intramembrane proteolysis by PS/ γ -secretase (24). We prepared cells stably expressing NEXT and wt or a dominant-negative form of PS1 (PS1 D385N) (51). A 30-min pulse with [³⁵S]methionine followed by a 2-h chase revealed

production of an ~70-kDa NICD band that completely disappeared upon elimination of PS/ γ -secretase function (Fig. 2D, upper panel). Because degradation of NICD is mediated by the ubiquitin-proteasome pathway (8, 40, 41), we added a potent proteasome inhibitor mixture consisting of lactacystin, MG262, and NLVS (Fig. 2D, middle and lower panels). The resulting cell lysates were immunoprecipitated with antibody mN1A, separated by SDS-PAGE, and analyzed by immunoblotting with anti-NT-V or anti-NT-S. The anti-NT-V and anti-NT-S antibodies specifically detected the PS-dependent production of NICD-V and NICD-S(+3), respectively (Fig. 2D, middle and lower panels; see Fig. S2C in the supplemental material). We also confirmed that both NICD-V and NICD-S(+3) are produced in cells in the absence of the proteasome inhibitor mixture (see Fig. S2D in the supplemental material).

S3 cleavage during Notch signaling produces distinct molecular species of NICD. Because ligand-induced degradation of Notch receptors is initiated at the plasma membrane (PM),

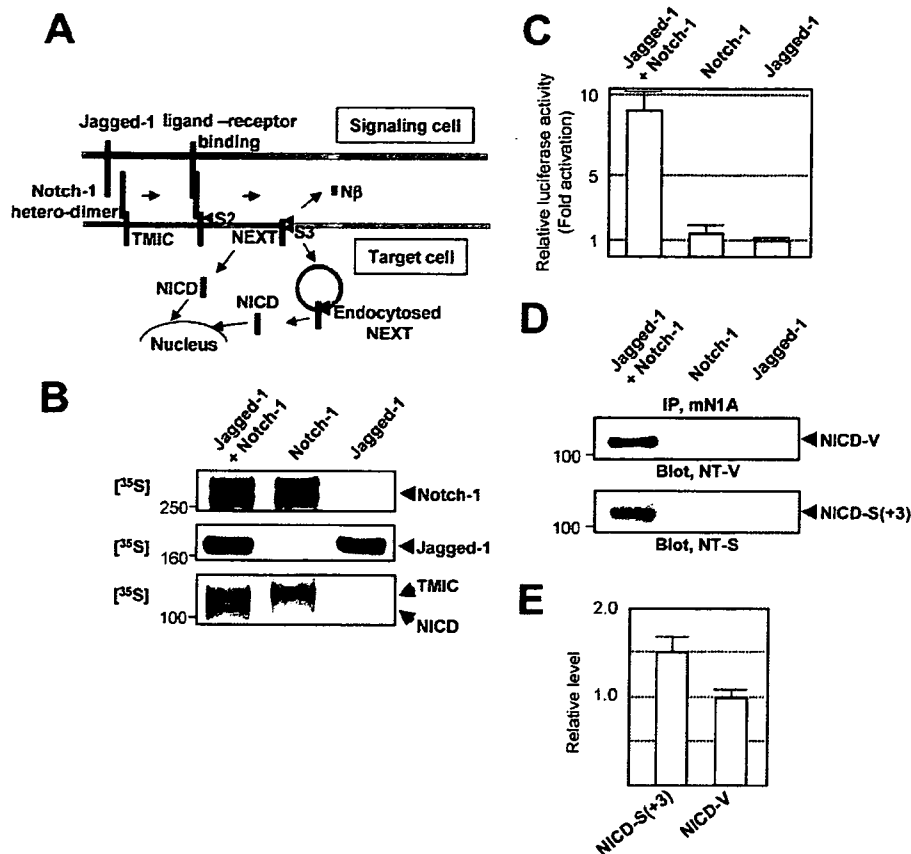

FIG. 3. Detection of different NICD species during Notch signaling. (A) Schematic representation of Notch signaling. (B) Notch signaling in cell culture. CHO(r) cells stably expressing Jagged-1 or Notch-1 were used. Expression of Notch-1 (top panel) and Jagged-1 (middle panel) was determined by a 1-h pulse experiment, followed by immunoprecipitation using antibodies mN1A and H114, respectively. The precipitated proteins were analyzed by SDS-PAGE, followed by autoradiography. A 1-h pulse/2-h chase experiment detected a ~110-kDa NICD band only when the cells were cocultured (bottom panel). (C) Notch signaling was measured using a dual luciferase assay. The relative luciferase activity of Jagged-expressing cells was defined as 1.0. Values represent means \pm standard deviations ($n = 3$). (D) In the presence of the proteasome inhibitors, both NICD-V (upper panel) and NICD-S(+3) (lower panel) were detected during Notch signaling. The bands were detected as described for Fig. 2D. (E) Relative levels of NICD-S(+3) and NICD-V generated during Notch signaling. The relative levels were calculated based on the standard curve shown in Fig. 2B.

intramembrane proteolysis of Notch-1 is thought to occur at restricted subcellular locations, such as the PM and endocytosed vesicles (13, 17, 20) (Fig. 3A). We prepared cells stably expressing either Jagged-1 (a Notch ligand) or full-length Notch-1 and then cocultured them. We determined the extent of Notch signaling using a luciferase reporter assay in cells expressing a newly improved construct, *HES-Y* (see Materials and Methods for details). Pulse-chase experiments revealed that upon coculture, sequential endoproteolysis of Notch-1 occurs, producing the NICD band (Fig. 3B, bottom panel). Moreover, when the cells were cocultured, we observed concomitant activation of the *HES-1* promoter (Fig. 3C). The results therefore demonstrate Notch-1 signaling in cell culture. Using this assay system, we investigated whether NICD-S(+3) and NICD-V are indeed generated during Notch signaling. Strikingly, upon coculture, both NICD-V and NICD-S(+3) were detected (Fig. 3D, upper and lower panels). The intensities of the bands indicated that 1.5-fold more NICD-S(+3) than NICD-V was produced (Fig. 3E). Therefore, the results

indicated that there are multiple forms of NICD produced during Notch signaling.

We next tried to detect the NICD-V and NICD-S(+3) in fetal (embryonic day 12, whole embryo without internal organs) and adult (brain) mouse tissues (Fig. 4). Nuclear extracts from these tissues were immunoprecipitated with mN1A, which specifically recognizes intracellular domain of Notch-1 but not Notch-2, -3, or -4. The precipitated proteins were then analyzed by SDS-PAGE, followed by immunoblotting with anti-NT-V or anti-NT-S antibodies. As shown in Fig. 4A, we clearly found both NICD-V (upper panel) and NICD-S(+3) species (lower panel) in the fetal mouse tissues, but these species were barely detectable in adult brains. This is consistent with the finding of a high level of Notch signaling in fetal mouse tissue (22). Moreover, we successfully detected the same NICD-V and NICD-S bands in the mouse embryo even when the combination of antibodies used for immunoprecipitation and immunoblotting was swapped (Fig. 4B). Therefore, the results indicated that multiple forms of NICD are produced in vivo.

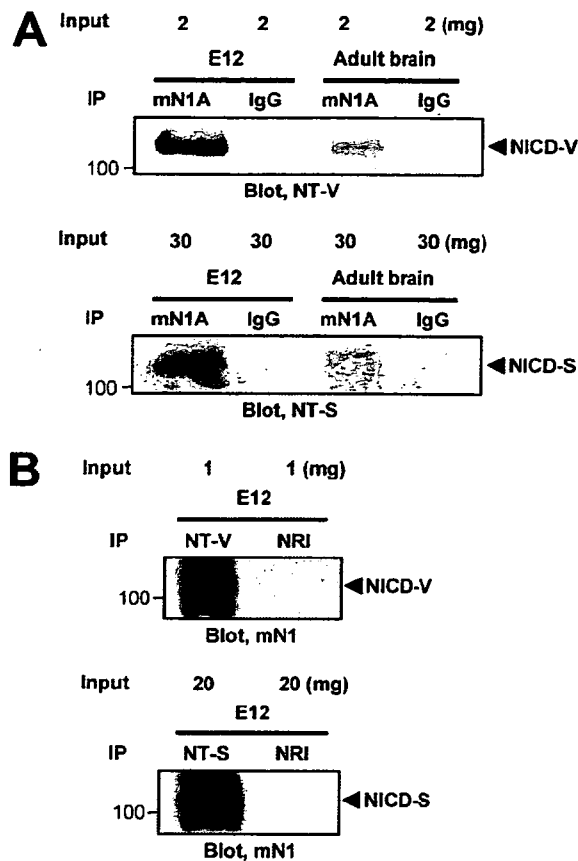

FIG. 4. Detection of NICD-V and NICD-S(+3) in vivo. The indicated amounts of nuclear extracts were loaded for immunoprecipitation. IgG and NRI, isotype-matched immunoglobulin and normal rabbit immunoglobulin, respectively.

Transactivation of the HES-1 promoter by NICD-S(+3) is much weaker than transactivation by NICD-V in living cells. The stability of polypeptides degraded by the ubiquitin-proteasome pathway depends on the N-end rule, where an N-terminal valine is a stabilizing residue and an N-terminal serine is destabilizing (2, 12). Therefore, we examined whether the intensity of Notch signaling differs for NICD-V and NICD-S(+3) in living cells. We loaded *HES-Y*-transfected cells with equal amounts of purified NICD-V or NICD-S(+3) (see Fig. S3 in the supplemental material). After a 1-h loading period, the cells contained similar levels of each NICD species (Fig. 5A). Induction of Notch signaling by chasing the loaded cells for 4 h (signaling period) resulted in much less luciferase activity in the NICD-S-loaded cells than in NICD-V-loaded cells, demonstrating that NICD-S(+3) is much weaker than NICD-V at activating the promoter in living cells (Fig. 5B, left panel).

We next investigated whether the rates of degradation by the proteasome pathway differ for the various species of NICD in an in vitro assay. We incubated recombinant NICD-V or NICD-S(+3) (34) with rabbit reticulocyte lysate (Promega) (12) and examined the levels of the two types of NICD by immunoblotting (Fig. 5C). Our results indicated that NICD-S(+3) is much less stable than NICD-V (Fig. 5D). Moreover,

following the proteasome inhibitor treatment, the relative luciferase activities in NICD-S- and NICD-V-loaded cells turned out to be almost the same (Fig. 5E). Collectively the results suggest that unstable NICD-S(+3) may have a much weaker ability than stable NICD-V to mediate intracellular signaling.

The precision of S3 cleavage is distinct in the subcellular locations where it occurs. A previous study showed that the precision of ϵ cleavage of β APP, which topologically corresponds to S3 cleavage of Notch-1, differs before and after endocytosis (11). To determine whether S3 cleavage precision differs on PM and endosomes, we performed the cell-free assay using organelles separated by iodixanol gradient fractionation from NEXTAC-expressing HeLa cells (11). Fractions from a 2.5% to 25% linear iodixanol gradient were examined by immunoblotting with antibodies to early endosome antigen 1 (endosome marker), Na-K ATPase (PM marker), GM130 (Golgi marker), or nicastrin (a component of the PS complex) (Fig. 6A). NICD(Δ C) was generated in the cell-free assay using membranes collected by centrifugation from the endosome-rich (fraction 3) and the PM-rich (fraction 7) fractions and analyzed by immunoprecipitation/MALDI-TOF MS. Remarkably, the relative ratio of NICD-V(Δ C) to NICD-S(+3)(Δ C) was much higher in the PM-rich fraction than in the endosome-rich fraction (Fig. 6B). This indicates that cleavage at S3-V, which generates the longer NICD-V(Δ C), and at S3-S(+3), which generates the shorter NICD-S(+3)(Δ C), occurs predominantly on the PM and endosomes, respectively. This is very similar to the case of ϵ cleavage of β APP (11). Subsequently, we investigated the effect of endocytosis on the precision of S3 cleavage. To down-regulate endocytosis, we used cells that express a dominant-negative mutant of dynamin-1 (Dyn-1 K44A) upon tetracycline withdrawal (Fig. 6C) or treatment with bafilomycin A1 (11) (see Fig. S4 in the supplemental material). When endocytosis was strongly inhibited, the precision of S3 cleavage changed drastically, so that the S3-V site instead of the S3-S(+3) site became the major site of cleavage in the cell-free assay (Fig. 6C; see Fig. S4A in the supplemental material). These results from the cell-free assay suggest that generation of stable NICD-V and unstable NICD-S occur predominantly on the PM and endosomes, respectively.

The precision of S3 cleavage changes in parallel with the rate of endocytosis in target cells. Next, we investigated whether these phenomena also occur in living cells. We examined the influence of the rate of endocytosis of NEXT by altering the expression of Dyn-1 K44A in living cells (Fig. 7A). Measurement of biotinylated transferrin uptake revealed various rates of endocytosis in Dyn-1 K44A-expressing cells (Fig. 7B). Strikingly, we found that the ratio of S3-V to S3-S(+3) is low in cells with a high rate of endocytosis and, conversely, that the ratio is high in cells with a low rate of endocytosis (Fig. 7C), which is consistent with the result from the cell-free assay (Fig. 6C). We observed a similar change in the S3 cleavage when endocytosis was blocked with bafilomycin A1 (see Fig. S4B in the supplemental material). Therefore, it appears that the precision of S3 cleavage changes in parallel with the rate of endocytosis, and relative generation of stable NICD-V increases as the rate of endocytosis decreases.

Because Notch signaling is associated with endocytosis of Notch receptors and/or Notch ligands during development (3, 28, 35, 40, 43), we next examined the effect of the change in S3

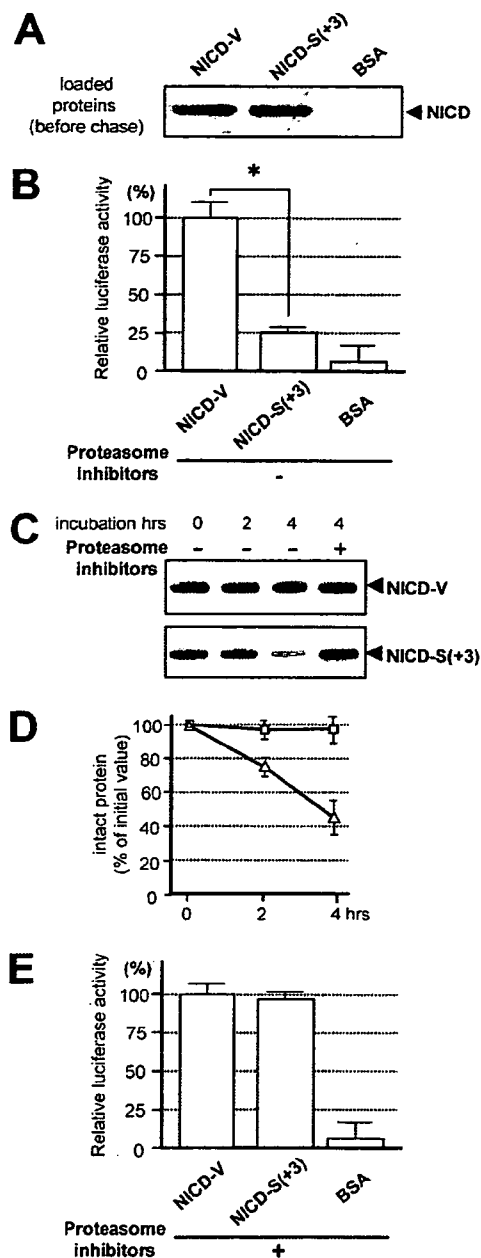

FIG. 5. Characterization of the NICD species. (A) Loading of cells with NICD. HeLa cells (2.5×10^5) were loaded with $5 \mu\text{g}$ of purified NICD-V, NICD-S(+3), or BSA (control). The cells were collected 1 h after the addition of the Chariot macromolecule complex (defined as the loading period). (B) Assay of Notch downstream signaling induced by the NICD species. The NICD-loaded cells from panel A were chased for 4 h and collected, and Notch downstream signaling was assayed. The values were corrected for background luciferase activity ($0.5 \mu\text{g}$ of β -galactosidase-loaded cells), and the luciferase activity in the NICD-V-loaded cells was defined as 100%. Values represent means \pm standard deviations ($n = 3$). The asterisk indicates that the relative luciferase activity in NICD-V-loaded cells is statistically different than that in NICD-S(+3)-loaded cells ($P < 0.001$). Similar results were obtained using cells expressing pGa981-6 (data not shown). (C) Stability of recombinant NICD species in rabbit reticulocyte lysate. Note that the degradation of NICD-S(+3) was inhibited in the presence of proteasome inhibitors. (D) Levels of intact NICDs in the lysates during in vitro degradation. The amount of intact polypeptide was determined using a standard curve of the chemiluminescence

precision on the intensity of Notch signaling. Surprisingly, we observed a higher intensity of Notch signaling in cells in which the rate of endocytosis of NEXT was lower (Fig. 7D; see Fig. S4C in the supplemental material). These results suggest that the rate of endocytosis in target cells could affect the intensity of intracellular Notch signaling by changing the precision of S3 cleavage and thus its stability.

Mutations around S3 can induce changes in the precision of the cleavage. S3 mutations, such as the Val \rightarrow Gly mutation (V1744G mutant) and the Lys \rightarrow Arg mutation (K1749R mutant), cause a decrease in the NICD level (13, 15). To date, this reduction has been considered to be due to decreased NICD generation. However, since we revealed that multiple NICD species with different stabilities are generated, we investigated whether these mutants also change the S3 cleavage precision, which would accelerate degradation of NICD. First, we determined the precision of the S3 cleavage of the Val \rightarrow Gly mutant version of NEXTAC in the cell-free assay (Fig. 1C). Strikingly, this mutant was degraded mainly into NICD-L(+1)(Δ C), which has Leu1745 (murine Notch-1 numbering) at its N terminus (Fig. 8A). Therefore, it appears that the Val \rightarrow Gly mutation causes not only a complete loss of stable NICD-V, but also a dramatic shift in the major product from NICD-S(+3) to NICD-L(+1). We next examined whether NICD-L(+1) behaved like NICD-S(+3) in cellular signal transduction. Like NICD-S(+3), NICD-L(+1) was much weaker than NICD-V at inducing promoter activation in living cells (Fig. 8B). Moreover, our in vitro degradation assay revealed that NICD-L(+1) was much less stable than NICD-V (Fig. 8C). Thus, our in vitro experiments suggested that NICD-L(+1) and NICD-S(+3) are both unstable and have similar effects on Notch signaling but that their effects are distinct from those of NICD-V. We further investigated whether the precision change in the mutant is also observed in living cells. To specifically detect NICD-L(+1), we generated anti-NT-L, an N-terminal capping antibody (see Fig. S5 in the supplemental material). As is clearly shown in Fig. 8D, although almost no NICD-V was detected, a substantial amount of NICD-L(+1) was detected in the Val \rightarrow Gly version of NEXT-expressing cells. These results indicate that the relative production of unstable NICDs with respect to stable NICD increases in the mutant NEXT cells due to change of the S3 cleavage precision.

The Lys \rightarrow Arg mutant NEXT (the K1749R mutant) is neither monoubiquitinated nor endocytosed (13). This mutant, like the Val \rightarrow Gly mutant, causes decreased NICD levels in cell culture (13). Analysis to determine the precision of the S3 cleavage of the Lys \rightarrow Arg mutant version of NEXTAC was performed in the cell-free assay. Surprisingly, the Lys \rightarrow Arg

intensities of the bands versus their concentrations (data not shown). Squares and triangles indicate the means for NICD-V and NICD-S(+3), respectively. Values represent means \pm standard deviations ($n = 3$). (E) Assay of Notch downstream signaling induced by the NICD species in the presence of the proteasome inhibitor mixture. Experiments were performed as described for panel B in the presence of the proteasome inhibitor mixture. The values were corrected for background luciferase activity ($0.5 \mu\text{g}$ of β -galactosidase-loaded cells), and the luciferase activity in the NICD-V-loaded cells was defined as 100%. Values represent means \pm standard deviations ($n = 3$).

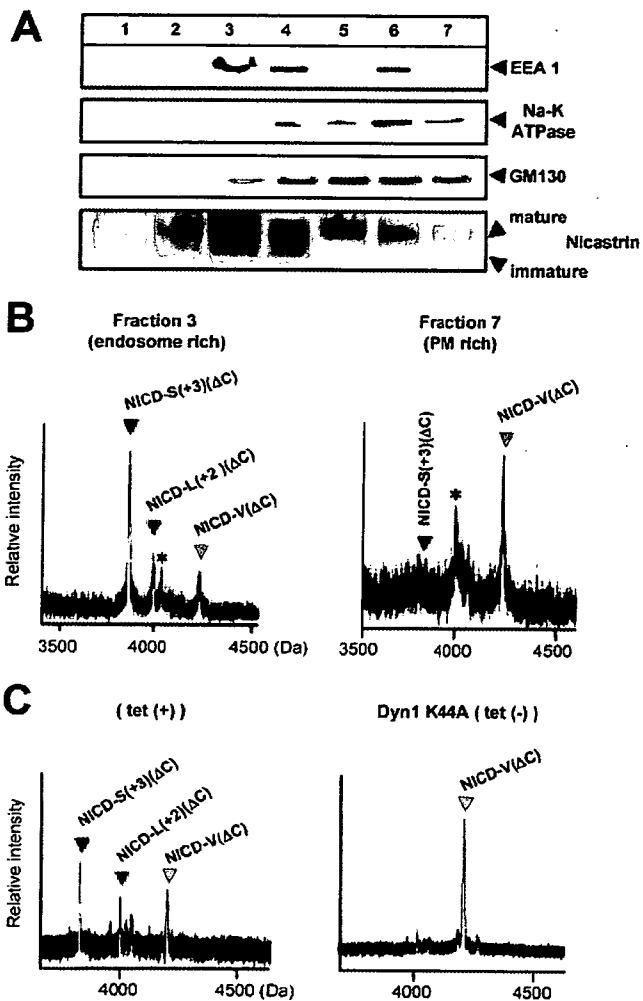

FIG. 6. Subcellular locations where S3-V and S3-S(+3) cleavages occur. (A) Fractions from a 2.5% to 25% linear iodixanol gradient examined by immunoblotting with the indicated antibodies. (B) MS spectra of NICD(Δ C) generated in the cell-free assay using membranes collected by centrifugation from the endosome-rich (fraction 3) and the PM-rich (fraction 7) fractions. Asterisks indicate nonspecific peaks. (C) MS spectra of NICD(Δ C) generated in the cell-free assay. CMFs from HeLa cells stably expressing NEXT(Δ C) and conditionally expressing Dyn-1 K44A were used. The precision of PS-dependent cleavage at the TM-cytoplasmic border in HeLa (left panel) and K293 (Fig. 1C) cells was different, in agreement with a previous report (11).

mutant was found to be degraded mainly into NICD-L(+2)(Δ C), NICD-S(+3)(Δ C), and NICD-R(+5)(Δ C) species, which have unstable Leu1746, Ser1747, and the mutated Arg1749 at the N terminus, respectively (Fig. 8E). These results suggest that due to a dramatic change in the S3 cleavage precision, the Lys \rightarrow Arg mutation causes not only a decrease of NICD-V but also an increase of extra unstable NICD species besides NICD-S(+3). This finding is reminiscent of the S3 cleavage for the Val \rightarrow Gly mutant NEXT. Moreover, we studied whether NICDs in living cells expressing the Lys \rightarrow Arg mutant are composed mainly of unstable NICD species. Strikingly, in the cells stably expressing the mutant NEXT, the stable NICD-V was barely detectable (13), while substantial

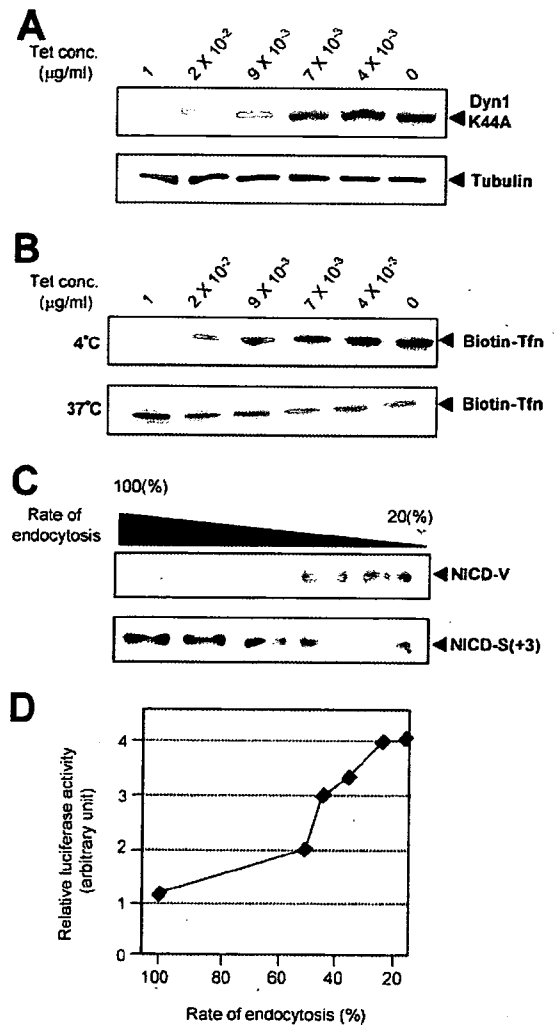

FIG. 7. Parallel change in the rate of endocytosis and the precision of S3 cleavage. (A) Expression of Dyn-1 K44A at various concentrations of tetracycline. Dyn-1 K44A/NEXT-coexpressing HeLa cells were cultured in medium with the indicated concentrations of tetracycline, and cell lysates were examined by immunoblotting with antibody 12CA5 (upper panel) or antitubulin (lower panel). The levels of Dyn-1 K44A increase as the concentration of tetracycline is decreased. (B) Various rates of endocytosis in Dyn-1 K44A expressing cells. Transferrin (Tfn) uptake assays were performed to measure the rate of endocytosis. The ratio of internalized Tfn (37°C; lower panel) to surface-bound Tfn (4°C; upper panel) in cells cultured in medium containing 1 μ g/ml of tetracycline was defined as 100%. The rate of endocytosis decreased to \sim 15% when tetracycline was completely withdrawn. (C) Effect of the rate of endocytosis on the NICD species. The calculated rates of endocytosis were 100%, 41%, 37%, 21%, and 15% in lanes 1 to 5, respectively. (D) A plot of the relative Notch downstream luciferase activity versus the rate of endocytosis at various tetracycline concentrations.

amounts of NICDs were generated in the presence of the proteasome inhibitor mixture (Fig. 8F, top and middle panels). Since almost no NICD is observed in the mutant cells without the inhibitor mixture, it is indicated that NICDs in the Lys \rightarrow Arg mutant-expressing cells are composed of unstable species (Fig. 8F, bottom panel). Therefore, the changes in the S3 cleavage precision induced by these S3 mutations are at

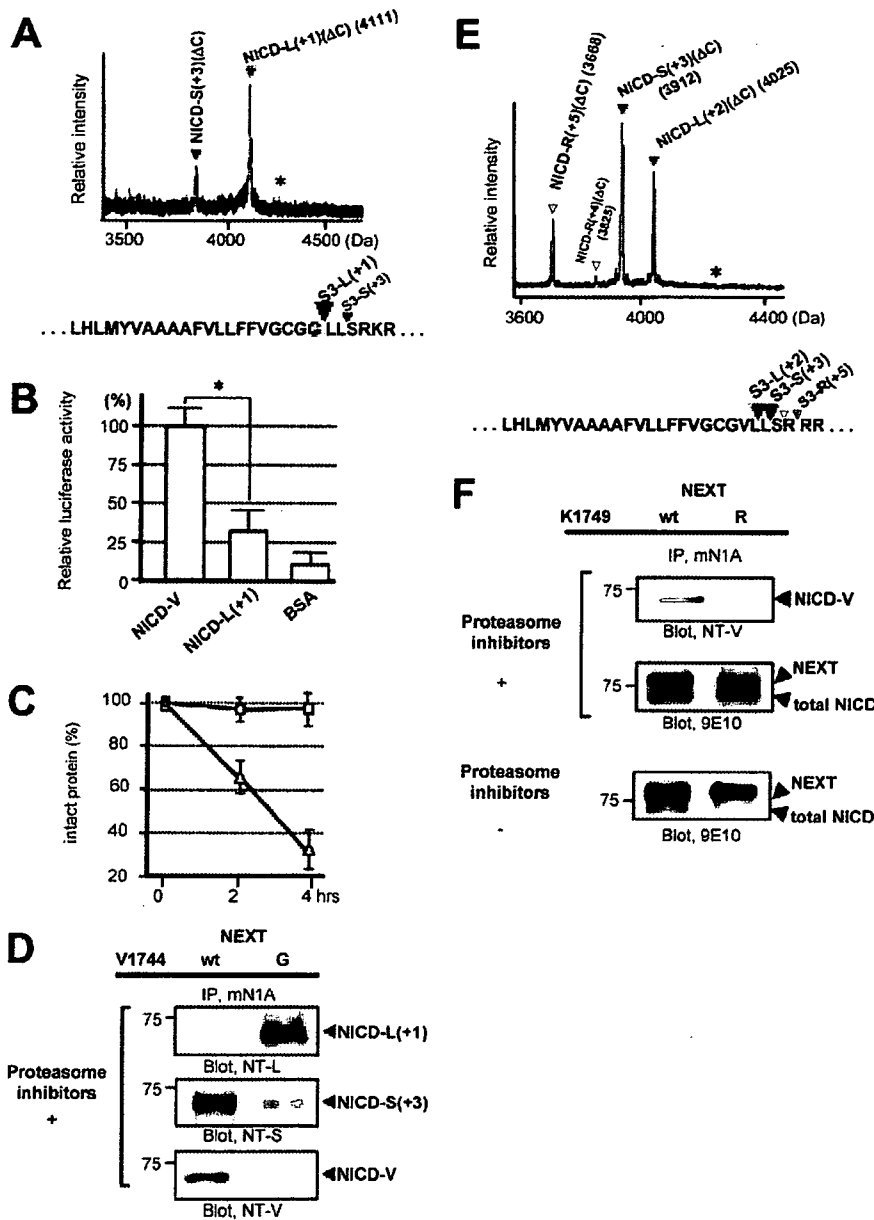

FIG. 8. Characteristics of the NICD species generated from the Val→Gly and the Lys→Arg mutants in cultured cells. (A) MS spectrum of de novo NICD(ΔC) generated from the Val→Gly mutant of NEXTΔC in K293 cells. The asterisk indicates the position of molecular mass corresponding to NICD-G(ΔC) species. Colored letters and inverted triangles show the mutation and proteolytic sites, respectively. (B) Assay of Notch downstream signaling induced by NICD-L(+1). Experiments were performed as described for Fig. 5B. The luciferase activity in the NICD-V-loaded cells was defined as 100%. Values represent means ± standard deviations. (*n* = 3). The asterisk indicates that the relative luciferase activity in NICD-V-loaded cells is statistically different than that in NICD-L(+1)-loaded cells (*P* < 0.001). (C) Degradation of NICD-L(+1) species in vitro. Experiments were performed as described for Fig. 5C but using NICD-L(+1) (triangles) and NICD-V (squares). Values represent means ± standard deviations (*n* = 3). (D) Generation of NICD-L(+1) and NICD-S(+3) in the Val→Gly mutant NEXT cells. K293 cells expressing either wt or the Val→Gly mutant NEXT were analyzed as described for Fig. 2D. (E) MS spectrum of de novo NICD(ΔC) generated from the Lys→Arg mutant of NEXTΔC in K293 cells. The asterisk indicates the position of molecular mass corresponding to NICD-V(ΔC) species. Colored letters and inverted triangles show the mutation and proteolytic sites, respectively. (F) Generation of unstable NICD species in the Lys→Arg mutant NEXT cells. K293 cells expressing either wt or the Lys→Arg mutant NEXT were analyzed as described for Fig. 2D (top and middle panels).

least partially responsible for the observed decrease in NICD level/Notch signaling in cultured cells.

Unlike several FAD-associated PS1 mutations, modifiers of PS/ γ -secretase do not induce changes in the precision of S3 cleavage. Many FAD PS mutations affect the precision of not

only γ but also ϵ cleavages of β APP and, therefore, generally increase the relative AICD ϵ 48/AICD ϵ 49 ratio as well as the A β 42/A β 40 ratio (38, 42). In addition, compounds that modify the activity of PS/ γ -secretase, including a subset of nonsteroidal anti-inflammatory drugs, cause reciprocal changes in rela-

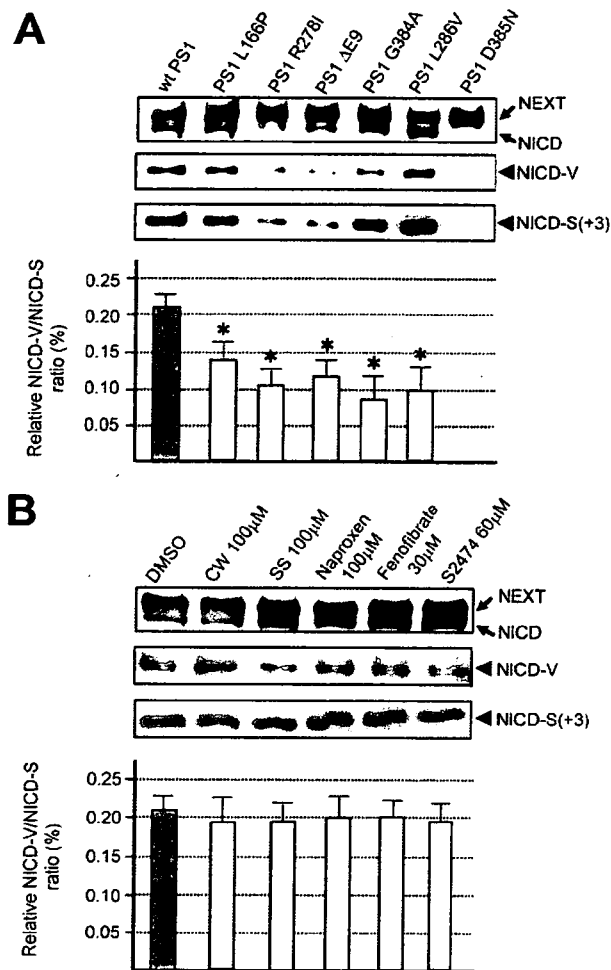

FIG. 9. Changes in the precision of S3 cleavage induced by FAD mutations in PS1. (A) Effect of several FAD PS1 mutations on the precision of S3 cleavage. K293 cells expressing the indicated PS mutant were transiently transfected with NEXT and analyzed as for Fig. 2D. The production of total NICD (first panel), NICD-V (second panel), and NICD-S(+3) (third panel) was assessed. Note that amount of total NICD was greatly reduced in PS1 R278I- and Δexon 9-expressing cells. The ratio of NICD-V to NICD-S(+3) in cells expressing wt PS1 or FAD mutants is shown in the bottom panel. Values represent means \pm standard deviations ($n = 3$). The asterisk indicates that the ratio of NICD-V to NICD-S(+3) in cells expressing PS1 FAD mutants is significantly different from that in wt PS1-expressing cells ($P < 0.002$). (B) Effect of PS/ γ -secretase modifiers on the precision of S3 cleavage. K293 cells stably expressing NEXT were treated with several PS/ γ -secretase modifiers at the indicated concentration for 24 h and analyzed as described for the first three panels in panel A. DMSO, dimethyl sulfoxide; CW, compound W (31); SS, sulindac sulfide (49). The ratio of NICD-V to NICD-S(+3) in the control and treated cells is shown in the bottom panel. Values represent means \pm standard deviations ($n = 3$).

tive production of A β 42 and A β 38 (19, 31, 49). Therefore, we investigated whether FAD PS mutations or PS/ γ -secretase modifiers affect the precision of S3 cleavage. To evaluate the precision change, we used the relative NICD-V/NICD-S ratio, mimicking the relative A β 42/A β 40 ratio in the case of γ cleavage. Immunoblotting using anti-NT-V or anti-NT-S revealed that cells coexpressing PS1 mutants and NEXT produce both

of the NICD species (Fig. 9A, top three panels). We found that the relative ratio of S3-V to S3-S(+3) cleavage was significantly reduced in some mutants (Fig. 9A, bottom panel). Subsequently, we examined the effects of PS/ γ -secretase modifiers and naproxen (Fig. 9B). Because the effective doses of the compounds for γ and S3 cleavage may differ, we performed dose-response experiments to select the highest working concentrations (data not shown). After confirming that the level of A β 42 in the medium was altered following a 24-h incubation with each compound (data not shown), we analyzed the cell lysates for the presence of NICD-V and NICD-S(+3) (Fig. 9B). In contrast to the case for the FAD mutants, the relative ratio of S3-V to S3-S(+3) cleavage was unchanged by the modifiers. These results suggest that γ -secretase modifiers do not affect the precision of intramembrane proteolysis by PS/ γ -secretase.

DISCUSSION

The current studies suggest a novel mode by which the intensity of Notch signaling is regulated. We found that intracellular Notch signaling molecules (NICDs) in target cells can be divided into a stable one that transmits a substantial signal and unstable ones that transmit a much weaker signal, depending on the specific site of S3 cleavage. Therefore, Notch signaling intensity transmitted by conversion of extracellular signaling into intracellular signaling could depend on the characteristics of the target cell. For example, although S3 cleavage occurs, cells might not receive a substantial Notch signal when predominantly unstable NICDs are generated. On the basis of our results, we propose that the precision of S3 cleavage by PS/ γ -secretase in the target cell is an important factor in determining the signaling intensity.

PS-dependent proteolysis on the TM of Notch-1 and β APP consists of dual cleavage at the S4/S3 and γ/ϵ sites, respectively (14, 31, 33). The finding of diversity in the site of S3 cleavage means that cleavage at all four sites in the TM of Notch-1 and β APP can vary. Thus, we suggest that the existence of variability in both the site and precision of cleavage may be a common feature of PS-dependent intramembrane proteolysis. Furthermore, we found that the precision of cleavage at S3 changes according to the subcellular location. On the PM, cleavage is more likely at S3-V, whereas on endosomes, cleavage is more likely at S3-S(+3), which is more C terminal. Interestingly, we have obtained very similar results regarding the cleavage of β APP at the ϵ site (11). The precision of cleavage at the ϵ site changes depending on the subcellular location (11). The ϵ 49 cleavage, which topologically corresponds to S3-V, occurs mainly on the PM, whereas the more C-terminal ϵ 51 cleavage, which topologically corresponds to S3-S, occurs mainly on endosomes. Therefore, we have demonstrated that such subcellular location-dependent changes in the precision of the cleavage by PS/ γ -secretase are common to the substrates. These findings suggest that such changes reflect a functional alteration of PS/ γ -secretase in each subcellular location.

S2 cleavage upon ligand binding should occur on the PM of the target cells, but whether the subsequent S3 cleavage occurs on the PM or after endocytosis remains controversial (13, 17, 20, 46). The results of the current study suggest that (i) S3 cleavage occurs in both subcellular fractions in cell culture and

(ii) S3-V cleavage, which generates stable NICD-V, occurs predominantly on the PM, whereas S3-S(+3) cleavage, which generates unstable NICD-S(+3), occurs predominantly on endosomes. We also found that the intensity of Notch signaling changes along with the extent of endocytosis, perhaps due to a change in the precision of S3 cleavage. Therefore, our results suggest that NICD generation on the PM and endosomes increases and decreases the intensity of Notch signaling, respectively. Reports that Sanpodo positively regulates Notch signaling on the PM and that Numb, a negative regulator, promotes endocytosis of Notch receptors and/or Sanpodo are consistent with our findings (3, 28). A previous study showed that *Drosophila* with a mutation in *shibire*, which encodes a homolog of dynamin, has a phenotype indicating a loss of Notch function (43). Further study to solve the contradiction is necessary.

Elimination of either Notch or PS function causes a strong Notch loss-of-function phenotype in vivo (23, 41). Knock-in mice with the S3 (Val \rightarrow Gly) mutant of Notch-1 display a hypomorphic Notch phenotype, possibly due to reduced Notch signaling caused by a decrease in the intracellular NICD level (6, 15, 39). This reduction in the level of NICD polypeptides could be due to decreased generation and/or increased degradation (4, 6). Previously, NICD was considered to be a single polypeptide mediating a single type of signaling, implying that the lower level of NICD is due to a decrease in its generation; however, we found that the N termini of NICDs may play critical roles in their stabilities and thus signaling intensities.

Among S3 mutants of Notch-1, the Lys \rightarrow Arg mutant NEXT is neither monoubiquitinated at Arg1749 nor endocytosed (13). Concurrently, the NICD-V level in the cells expressing this mutant is low (13). In this paper, we demonstrated that the Lys \rightarrow Arg mutation also causes a drastic change in the precision of the S3 cleavage, which results in a drastic decrease of NICD-V generation on the PM. This explanation, if valid, resolves the discrepancy between the two studies.

Both stabilizing (Val, Met, or Gly) and destabilizing amino acid residues seem to be conserved in Notch orthologs of various organisms (see Table S2 in the supplemental material). This suggests that both stable and unstable intracellular Notch signaling exists in many species. Previous studies have indicated that differences in the intensity, duration, and timing of Notch signaling in target cells affect cell fate decisions (7, 26). Furthermore, the signaling by a molecule is dependent on its lifetime in the cell, and the lifetime should be short enough for the target cell to be able to rapidly change the extent of signaling (22). Therefore, target cells in different contexts may convert extracellular signals to various relative amounts of short- and long-term Notch signals.

FAD PS mutations generally increase the generation of A β 42 (42). This pathological gain of function of PS is due to a change in the precision of γ cleavage, resulting in an increase in cleavage at γ 42 (42). PS/ γ -secretase modifiers can up- or down-regulate the cleavage at γ 42 (19, 31, 49). In both cases, the modifiers have reciprocal effects on the production of A β 42 and A β 38 (31, 49). In this study, we found that several FAD PS1 mutants change the precision of S3 cleavage but that the PS/ γ -secretase modifiers do not. These findings are consistent with previous studies showing that the precision of γ cleavage in β APP is altered by certain FAD PS mutations (38)

and that Notch processing is unaffected by nonsteroidal anti-inflammatory drugs that can reduce A β 42 generation (45, 49). PS/ γ -secretase modifiers could thus affect the precision of the intramembrane proteolysis differently from PS FAD mutations.

Because up-regulation in Notch signaling is involved in a subset of malignancies (10, 37, 47, 50), γ -secretase inhibitors have been considered for the treatment of cancer; however, inhibitors would cause the accumulation of substrates (i.e., NEXT), inevitably producing a "rebound effect," where the concentration of NICD would increase. Therefore, compounds that alter the precision of S3 cleavage and specifically inhibit the generation of stable NICD-V may be more effective therapeutic agents.

Abstract

Lithium is one of the most commonly used drugs for the treatment of bipolar disorder. To prescribe lithium appropriately to patients, predictors of response to this drug were explored, and several genetic markers are considered to be good candidates. We previously reported a significant association between genetic variations in the breakpoint cluster region (BCR) gene and bipolar disorder. In this study, we examined a possible relationship between response to maintenance treatment of lithium and Asn796Ser single-nucleotide polymorphism in the BCR gene. Genotyping was performed in 161 bipolar patients who had been taking lithium for at least 1 year, and they were classified into responders for lithium monotherapy and non-responders. We found that the allele frequency of Ser796 was significantly higher in non-responders than in responders. Further investigation is warranted to confirm our findings.

Keywords: BCR (breakpoint cluster region); Bipolar disorder; Lithium; SNP (single-nucleotide polymorphism)

1. Introduction

Bipolar disorder (BPD) is one of the most distinct syndromes in psychiatry, which is characterized by recurrent episodes of

mania and depression. Three representative mood stabilizers, lithium, valproate and carbamazepine, are used worldwide for its treatment, and American Psychiatric Association guideline listed lithium as a first line agent (American Psychiatric Association, 2002). However, these treatments are associated with variable rates of efficacy and often with intolerable side effects. Therefore, many researchers explored psychopathological and biological markers for good response to lithium treatment (Gelenberg and Pies, 2003; Ikeda and Kato, 2003). To date, several studies investigated possible molecular predictors of lithium efficacy. The functional polymorphism in the upstream regulatory region of the serotonin transporter gene (5-HTTLPR) has been associated with lithium efficacy in two independent studies (Serretti et al., 2001;

doi:10.1016/j.pnpbp.2007.08.010

Del Zompo et al., 1999), although the polymorphism associated with better lithium response was opposite. Other numerous genetic variants including catechol-*O*-methyltransferase were not associated with lithium response (Serretti et al., 2002). The association between prophylactic lithium response and the polymorphism of the brain-derived neurotrophic factor (BDNF) gene was reported (Rybakowski et al., 2005); however, this association was not replicated in subsequent studies (Masui et al., 2006; Michelon et al., 2006).

We previously reported a significant association between genetic variants in the breakpoint cluster region gene (*BCR*), which is located on chromosome 22q11, and BPD (Hashimoto et al., 2005). The *BCR* is highly expressed in hippocampal pyramidal cell layer and dentate gyrus (Fioretos et al., 1995), and encodes a Rho GTPase-activating protein (GAP), which inactivate the Rho GTPase playing an important role in neuronal development (Diekmann et al., 1991; Negishi and Katoh, 2002). The A2387G single-nucleotide polymorphism (SNP) in the *BCR* gene [National Center for Biotechnology Information (NCBI) SNP ID: rs140504] is the non-conservative SNP giving rise to an amino acid change of asparagine to serine at codon 796 (Asn796Ser; NCBI Protein ID: NP_004318). Ser796 allele showed a significant association with BPD and stronger evidence for an association with bipolar II disorder (BP-II) than bipolar I disorder (BP-I) (Hashimoto et al., 2005). It has been reported that patients with BP-II have greater number of abnormal mood episodes and comorbidity of other psychiatric illnesses than patients with BP-I (Ayuso-Gutierrez and Ramos-Brieva, 1982; Berk and Dodd, 2005). These clinical features of BP-II have been also considered as markers for poor response to lithium treatment (Ikeda and Kato, 2003). Therefore, Ser796 allele of the *BCR* gene may contribute to poorer response to lithium therapy in BPD.

In this study, we examined the possible association between prophylactic effect of lithium and Asn796Ser SNP of the *BCR* gene in Japanese patients with BPD.

2. Methods

2.1. Subjects

Subjects were 161 patients with BPD (83 patients were BP-I, and 78 patients were BP-II). Consensus diagnosis was made for each patient by at least two psychiatrists according to the Diagnostic and Statistical Manual of Mental Disorders 4th edition (DSM-IV) criteria. The presence of concomitant diagnoses of mental retardation, drug dependence, or other Axis I disorder, together with somatic or neurological illnesses that impaired psychiatric evaluation, represented exclusion criteria. They were composed of 76 males and 85 females with mean age of 48.2 ± 12.8 years (mean \pm S.D.). All the subjects were biologically unrelated Japanese. Patients had been treated with lithium carbonate and its serum concentration was maintained between 0.4 and 1.2 mEq/L at least for one year, in a completely naturalistic setting.

Response to lithium treatment was retrospectively determined for each patient from all available information including clinical interview and medical records, by at least two psychiatrists, and

the patients were classified into lithium responders and non-responders. The phenotype definition of lithium prophylaxis is a very difficult issue. Lithium responders were defined as those patients without any affective episodes during the maintenance period of lithium mono-therapy. During the maintenance period, the addition of antidepressants, antipsychotics, or anticonvulsants was regarded as a relapse, and excluded from the responder group. However, coadministration of hypnotics for sleep disturbance was allowed, and was not regarded as a relapse when subsequent affective episode did not appear.

Our definition of response to lithium treatment is full response without any affective episode during lithium treatment. This definition is similar to "excellent lithium responders" used as clinical endophenotypic marker of BPD in some molecular-genetic research (Rybakowski et al., 2005; Mamdani et al., 2007). On the other hand, recurrence index [number of episodes/duration of illness (years)] before and during lithium treatment is a better method to measure the response to lithium including partial response (Gasperini et al., 1993; Serretti et al., 2002). However, more clinical information is necessary to calculate the recurrence index. We investigated the association between the change of recurrence index and clinical variables in parts of total subjects (24 patients) whose recurrence pattern were clearly established during more than 1 year [mean 5.8 ± 5.0 (range 1.3–21.0) years] before lithium treatment. They were composed of 9 BP-I and 15 BP-II patients, whose age of onset was 35.4 ± 9.5 years old, duration from onset of illness to lithium treatment was 9.5 ± 7.0 (range 1.3–22.0) years, number of episodes which could be clearly identified before lithium treatment was 16.3 ± 30.3 (range 3.0–150.0), duration of lithium treatment was 6.0 ± 4.3 (range 1.0–14.3) years, number of episodes during lithium treatment was 6.8 ± 6.0 (range 0.0–26.0) and recurrence index before and during lithium were 2.7 ± 2.8 (range 0.6–14.2) and 1.8 ± 1.5 (range 0.0–5.3), respectively.

After complete description of the study, written informed consent was obtained from every subject. The study protocol was approved by institutional ethics committees.

Table 1
Clinical characteristics of subjects, sorted by response to lithium treatment

	Response to lithium treatment		
	Responders (N=43)	Non-responders (N=118)	
Subtype			χ^2 test
BP-I	29 (34.9%)	54 (65.1%)	$p < 0.05$
BP-II	14 (18.0%)	64 (82.0%)	
Gender			NS
Male	25 (32.9%)	51 (67.1%)	
Female	18 (21.2%)	67 (78.8%)	
Age at last observation	54.4 ± 11.8	46.1 ± 12.4	t -test
Age of onset	41.5 ± 13.6	32.9 ± 10.7	$p < 0.01$
Duration of illness	12.9 ± 9.0	13.2 ± 9.9	NS

Continuous values were represented as the mean \pm SD. BP-I=bipolar I disorder, BP-II=bipolar II disorder, NS=not significant.

Table 2
Allele frequencies and genotype of the Asn796Ser polymorphism of the BCR gene and response to lithium treatment

Response to lithium treatment	Allele frequency		χ^2 test <i>p</i> value (OR)	Genotype			χ^2 test <i>p</i> value
	Asn	Ser		Asn/Asn	Asn/Ser	Ser/Ser	
Responders (<i>n</i> =43)	49 (57.0%)	37 (43.0%)	0.024 (1.77)	35 (81.4%)	8 (18.6%)	0.049	
Non-responders (<i>n</i> =118)	101 (42.8%)	135 (57.2%)		77 (65.3%)	41 (34.7%)		
Total patients (<i>n</i> =161)	150 (46.6%)	172 (53.4%)		112 (69.6%)	49 (30.4%)		

OR: Odds ratio.

2.2. Genotyping

Venous blood was drawn from the subjects and genomic DNA was extracted from whole blood according to the standard procedures. The genotype of the Asn796Ser SNP (rs140504) of the BCR gene was determined by TaqMan 5'-exonuclease allelic discrimination assay, described previously (Hashimoto et al., 2005). Briefly, probes and primers for detection of the polymorphism were: forward primer 5'-AGCTGGACGCTTTGAA-GATCA-3', reverse primer 5'-TGGTGTGCACCTTCTCTCT-3', probe 1 5'-VIC-CCAGATCAAGAATGACAT-MGB-3', and probe 2 5'-FAM-CCAGATCAAGAGTGACAT-MGB-3'. PCR cycling conditions were: at 95 °C for 10 min, 50 cycles of 92 °C for 15 s and 60 °C for 1 min.

2.3. Statistical analysis

Difference in clinical characteristics between responders and non-responders to lithium treatment was analyzed using the χ^2 tests for categorical variables and *t* tests for continuous variables. The presence of Hardy–Weinberg equilibrium was examined by using the χ^2 test for goodness of fit. Subsequently, multiple logistic regression analysis was performed to correct background difference between responders and non-responders for lithium treatment. Possible predictors (genotype of the BCR gene, subtype of bipolar disorder, age of onset, age at last observation, and gender) were included in the original model. Backward stepwise regression was performed, and *p*-value greater than 0.10 was used for variable removal. Pearson coefficient of correlation test was used for comparison between recurrence index and clinical variables. The effect of the Asn796Ser SNP on recurrence index was assessed by analysis of variance (ANOVA). All *p*-values reported are two-tailed. Statistical significance was defined at *p*<0.05.

3. Results

Among 161 patients with BPD, 43 patients were determined as responders and 118 patients as non-responders for the maintenance treatment of lithium. The clinical characteristics sorted by response to lithium treatment and genotype distribution were presented in Table 1. There were significant differences between responders and non-responders in subtype of bipolar disorder (BPI and BPII), age at last observation, and age of onset.

The genotype distributions for the total patients, responders, and non-responders were in Hardy–Weinberg equilibrium (total

patients: $\chi^2=0.94$, *df*=1, *p*=0.33; responders: $\chi^2<0.001$, *df*=1, *p*=0.98; non-responders: $\chi^2=0.81$, *df*=1, *p*=0.37). Allele frequencies and genotype distributions of the Asn796Ser polymorphism of the BCR gene among responders and non-responders for lithium treatment are presented in Table 2. The Ser796 allele was in excess in the non-responders rather than responders ($\chi^2=5.09$, *df*=1, *p*=0.024; OR 1.77, 95% CI 1.08–2.92). Then, we examined patients homozygous for the Ser796 allele and the Asn796 allele carriers, separately. Patients homozygous for the Ser796 allele were significantly more common in the non-responders than the Asn796 carriers ($\chi^2=3.88$, *df*=1, *p*=0.049; OR 2.33, 95% CI 0.99–5.49). After backward stepwise regression, the final logistic regression model included subtype of bipolar (*p*<0.01), age of onset (*p*<0.01), and genotype which is separated to the Asn796 carrier and homozygous for the Ser796 (*P*=0.04).

We next investigated the association between lithium response using recurrence index and clinical variables in 24 subjects with BPD. The change of recurrence index before to during lithium treatment was not associated with subtype (*t*=0.79, *df*=22, *p*=0.44), age of onset (correlation coefficient=−0.29, *p*=0.17), duration from onset of illness to lithium treatment (correlation coefficient=0.12, *p*=0.57), duration during treatment (correlation coefficient=0.11, *p*=0.60), or the Asn796Ser SNP (*df*=2, *F*=0.03, *p*=0.97).

We also examined the association between age of onset and recurrence index before lithium treatment, which reflects severity of illness. There was a negative trend between age of onset and recurrence index (correlation coefficient=−0.37, *p*=0.074). Although difference among genotype of Asn796Ser SNP was not statistically significant, the number of Ser796 allele was associated with higher recurrence index before lithium treatment (Asn/Asn=1.63±1.19, Asn/Ser=2.89±0.84, and Ser/Ser=3.23±1.19. *df*=2, *F*=0.53, *p*=0.60). Therefore, the Ser796 allele might also be associated with both early onset and severity of illness, which could result in poorer lithium response.

4. Discussion

We investigated a possible association between the BCR gene and the prophylactic effect of lithium treatment in patients with BPD for the first time. As expected, our results suggested that lithium treatment might be less effective in patients homozygous for the Ser796 allele of the BCR gene than in patients with the Asn796 allele. In addition, allele frequencies of the Ser796 associated with poorer lithium response were 43.0%

in responders and 57.2% in non-responders. As allele frequency of the Ser796 in healthy subjects in our previous study was 48.1% (Hashimoto et al., 2005), allele frequency of the Ser796 of responders is similar to the general population.

Comparing clinical characteristics of responders and non-responders, there were more BPII patients in non-responder group. Clinical characteristics predicting poorer response to lithium therapy and that of BPII seem to overlap each other, but better lithium response in BPI is not universally accepted. We excluded any Axis I comorbidity in this study. This would leave in more typical bipolar II patients who would be more likely to respond to lithium, however, other clinical factors such as Axis II comorbidity might influence our results. The presence of positive family history of lithium responsive BPD has been reported as indicative of favorable response (Grof et al., 2002). However, it was not assumed that our sample size was enough to investigate this issue because only 8.7% of BPD had positive family history of the same disease in 1st degree relatives (Smoller and Finn, 2003). Therefore, information about family history of lithium response was not collected in this study.

Age at onset was also different between responders and non-responders, and early age of onset was associated with poorer response to lithium treatment in our subjects. This observation is consistent with recent meta-analysis (Kleindienst et al., 2005). As the objective of this study is to examine the association between response to lithium treatment and a SNP in the *BCR* gene, the differences in demographic parameters of responders and non-responders might not be preferable. Therefore, we conducted a multiple logistic regression analysis, and homozygous for the Ser796 allele of the *BCR* gene was still significantly associated with poorer response to lithium treatment.

The evaluation of lithium prophylaxis is considerably difficult because of complex clinical course of BPD, and each researcher has used different methodologies. Although our finding was based on the simple definition, in which lithium responders didn't have any affective recurrences during lithium, one of the limitation of this study is lack of detailed clinical information, e.g. duration from onset of illness to lithium treatment and number of episodes which could be clearly identified before lithium treatment in total subjects. To evaluate lithium efficacy including partial response, calculating recurrence index before and during lithium treatment is used in several researches. This would be a correct measure of lithium prophylaxis, but evaluating mood recurrence accurately before the first contact to mental professionals is difficult. We tried to evaluate lithium response with recurrence index; however, we could examine it in only 24 subjects out of 161 subjects due to the difficulty of collecting this clinical information. We did not find any association between the recurrence index and clinical variables and the SNP in the *BCR* gene, except for the trend between the recurrence index and age of onset. As these results were from subgroup analysis with smaller number, further investigation is needed in a larger sample size.

In this study, the same variant associated with the illness was also associated with poorer outcome. This situation is similar to that of the Val allele of the *BDNF* Val66Met polymorphism (Rybakowski et al., 2005), and it is possible that the *BCR* Ser796

and the *BDNF* Val66 alleles are associated with severer illness presentation. The trend between the recurrence index and age of onset in our subgroup analysis might imply this possibility. In case of the *BDNF* Val66Met SNP, the functional differences arisen from each allele were reported (Eagan et al., 2003). While biological functional of the *BCR* Asn796Ser SNP is still unknown, this SNP may produce functional difference in the brain, like the *BDNF* Val66Met SNP. To speculate this issue, it is noteworthy that this SNP is in the pleckstrin homology (PH) domain of the *BCR*. As PH domain is known for its ability to bind phosphatidylinositol and this binding regulates the activity of PH domain containing protein (Lemmon et al., 2002), signal transduction from inositol cycle to the *BCR* products might be affected by this SNP. As the *BCR* is RhoGAP, this change may influence on the activity of its downstream target, RhoGTPase, which activates many kind of effectors associated with constructing neuronal network, and subsequently influence on neuronal development. Additionally, as inositol cycle is considered as one of therapeutic targets of lithium (Harwood, 2005), this SNP could alter the clinical efficacy of lithium. To understand the mechanism of our findings, it is worth investigating whether the Asn796Ser SNP alters the binding ability of PH domain to inositol.

5. Conclusion

This is the first report demonstrating that long-term lithium treatment may be less effective in BPD patients homozygous for Ser796 allele of the *BCR* gene than in patients with the Asn796 allele. The limitations of this study are retrospective design without placebo control group, small sample size, and lack of clinical information such as presence of rapid cycling and/or psychotic symptoms, and detailed lithium levels. Further investigations are needed to confirm our findings.

Acknowledgements

The authors thank Ms. Tomoko Shizuno and Keiko Okada for their technical assistance. This work was supported in part by Grants-in-Aid from the Japanese Ministry of Health, Labor and Welfare, the Japanese Ministry of Education, Culture, Sports, Science and Technology, CREST (Core research for Evolutional Science and Technology) of JST (Japan Science and Technology Agency), Research on Health Sciences focusing on Drug Innovation of The Japan Health Sciences Foundation, and Japan Foundation for Neuroscience and Mental Health.

Duality of interest. The study sponsor had no involvement in study design, data collection, analysis, or interpretation, writing of the paper, or the decision to submit the paper for publication.
