Prognostic Factors in Influenza-Associated Encephalopathy

Takashi Nagao, MD,* Tsumo Morishima, PhD,* Hiroshi Kimura, PhD,† Syumper Yokota, PhD,‡ Nobuko Yamashita, PhD,* Takashi Ichiyama, PhD,§ Mana Kurihara, PhD,|| Chiaki Miyazaki, PhD,¶ and Nobuhiko Okabe, MD, PhD#

Background: Recently, reports of influenza-associated encephalopathy have increased worldwide. Given the high mortality and morbidity rates attributable to this severe neurologic complication of influenza, we conducted a nationwide study in Japan to identify the prognostic factors.

Methods: We retrospectively evaluated 442 cases of influenza-associated encephalopathy that were reported to the Collaborative Study Group on Influenza-Associated Encephalopathy, which was organized by the Japanese Ministry of Health, Labor, and Welfare in collaboration with hospitals, clinics, and local pediatric practices in Japan between 1998 and 2002. The outcome for each patient was classified as either survival or death. Predictors of death were identified using logistic regression analysis.

Results: Four major prognostic factors for death were found to be significant by multivariate analysis ($P < 0.05$) in the 184 patients for whom we had complete data: elevation of aspartate aminotransferase, hypoglycemia, the presence of hematuria or proteinuria, and use of diclofenac sodium.

Conclusions: We identified patients who had factors associated with a poor prognosis, and these findings might be clinically useful for the management of this illness.

Key Words: influenza-associated encephalopathy, hypoglycemia, diclofenac sodium, TNF- α

(*J Pediatr Infect Dis J* 2008;27:606-610)

Influenza-associated encephalopathy is a severe neurologic complication of influenza characterized by an abrupt onset of seizures and coma within a few days of developing a high fever.¹ The number of patients with influenza-associated en-

cephalopathy in Japan has increased in recent years, with more than 100 children younger than 6 years of age dying annually from this severe disease.¹ Recently, reports of influenza-associated encephalopathy have also increased worldwide.^{2,3}

Blood abnormalities, such as thrombocytopenia and elevated serum aspartate aminotransferase (AST), and brain computed tomography (CT) abnormalities are associated with poor outcome.⁴ Cyclooxygenase inhibitors, particularly aspirin, are known to cause Reye syndrome.^{4,5} In Japan, cyclooxygenase inhibitors such as diclofenac sodium and meloxicam acid, but not aspirin, are widely used as antipyretic drugs in children. We found that some nonsteroidal anti-inflammatory drugs, including diclofenac sodium and meloxicam acid, may be associated with the development of influenza-associated encephalopathy or may affect the severity of the disease.⁶ However, we were unable to thoroughly assess the relationship between the use of these medicines and prognosis.

The mortality rate of this disease is as high as 30%, without treatment.⁷ Therefore, for the administration of intensive care, it is important to identify the factors that affect its prognosis. We investigated 442 cases of influenza-associated encephalopathy reported from 1998 to 2002 in the Collaborative Study Group on Influenza-Associated Encephalopathy, organized by the Japanese Ministry of Health, Labor, and Welfare, and analyzed the prognostic factors using multivariate logistic regression analysis. We report several factors related to the poor prognosis of influenza-associated encephalopathy. To our knowledge, this is the first nationwide study of the prognostic factors of influenza-associated encephalopathy.

METHODS

Study Design. Questionnaires were developed by the Collaborative Study Group on Influenza-Associated Encephalopathy to assess the number of cases in all hospitals, clinics, and local pediatric practices (total of 3500 sites) between 1998 and 2002. Subsequently, a second questionnaire was sent to each applicable facility. The second questionnaire requested information on age, sex, virus type, history, flu vaccination record, peak body temperature, symptoms, laboratory data (CT findings, medication, diagnostic methods of influenza virus infection, and disease outcome). The age, peak body temperature, and laboratory data were provided directly by participating facilities; the other data were gathered during a telephone interview. The survey in our second questionnaire was conducted from January to March 2003.

Definition of Influenza-Associated Encephalopathy. The diag-

ratory data were obtained at admission. Recently, it has been reported that prognosis could be improved by therapies such as methylprednisolone pulse and hypothermia therapy.¹⁷ However, it was not possible to obtain information regarding these therapies for this study.

The study protocol was approved by the Institutional Review Board of Nagoya University Hospital.

Case Definition. Influenza infection was defined on the basis of a positive result on viral culture, viral antigen testing, or viral ribonucleic acid polymerase chain reaction, or a 4-fold or greater rise in paired serum antibody titer test (hemagglutination inhibition or complement fixation test). Patients who did not meet all the criteria were excluded from the study. In viral antigen testing, the influenza type could not be determined in several cases because the diagnosis was made using a viral antigen test that could not distinguish between types A and B influenza. Patients were defined as having influenza-associated encephalopathy if they showed clinical symptoms and signs compatible with acute encephalopathy, such as altered consciousness (ie, delirium, confusion, and cognitive impairment) or loss of consciousness (ie, deep coma, coma, semicoma, stupor, and somnolence), and if these symptoms persisted for more than 24 hours. Patients with meningitis, myelitis, and febrile convulsions without prolonged unconsciousness were excluded. Cases of postictal unconsciousness with prompt recovery were classified as febrile convolution. All of the cases reported as influenza-associated encephalopathy were reviewed thoroughly by members of the study group to confirm whether the diagnosis was appropriate. Doubtful cases were excluded from further analysis. The outcomes of influenza-associated encephalopathy were defined as survival or death. A survival outcome included all patients who were alive regardless of whether they had sequelae. In total, 442 influenza-associated encephalopathy cases in patients younger than 15 years of age were deemed appropriate for the study. Study participants provided informed consent or assented with parental consent.

Statistical Analysis. The data were analyzed using the Dr SPSS software package version 2 (SPSS Inc, Tokyo, Japan). Twenty variables were analyzed to formulate a predictive model for death caused by influenza-associated encephalopathy. The variables identified as significant at $P < 0.05$ using univariate logistic regression analysis were entered into a multivariate logistic regression model, and the least significant variables were sequentially removed. In the multivariate logistic regression analysis, the model was adjusted by age, sex, virus type, history of allergy, record of flu vaccination, and use of acetaminophen. In the multivariate logistic regression analysis, a value of $P < 0.05$ was considered statistically significant. A P value between 0.05 and 0.20 was considered to show a tendency toward being a factor for poor prognosis because a risk existed of eliminating important prognostic factors in the logistic regression if the P values were restricted to < 0.05 . Odds ratios with 95% confidence intervals were calculated.

RESULTS

Initially having influenza-associated encephalopathy, according to the primary questionnaire. In response to the second questionnaire, 585 cases from a total of 340 sites were reported and 442 cases in patients younger than 15 years of age deemed appropriate for further study. These included 97 patients who died and 345 patients who survived.

Of the 442 patients, 331 (74.9%) were between 1 and 6 years old, 232 were male, and 210 were female. No significant differences were observed in incidence or mortality between the sexes, 45 males and 52 females died. The death rates were 32.1%, 22.5%, 13.7%, and 16.4% in 1998–1999, 1999–2000, 2000–2001, and 2001–2002, respectively. We found 372 (84.2%) and 42 (9.5%) cases of type A and type B influenza, respectively. In the other 28 (6.3%) cases, the influenza type could not be determined. Fifty-four cases (22.1%) had a history of febrile convulsions.

Table 1 shows the numbers, percentages, odds ratios, and 95% confidence intervals from the univariate logistic regression analyses for the 20 variables divided by survival and death. In the univariate analyses, 14 variables had statistical significance ($P < 0.05$): peak body temperature of 40–41°C and $>41^\circ\text{C}$, diarrhea, ASI level of 100–500 IU/L and >500 IU/L, creatinine phosphokinase level of 200–1000 IU/L and >1000 IU/L, platelet count of $<10 \times 10^9/\mu\text{l}$, blood glucose level of <50 and >150 mg/dL, hematuria or proteinuria, CT showing edema, low-density areas, or hemorrhage, and use of diclofenac sodium and/or fentanyl acid for fever during influenza virus infection. These variables were retained for multivariate analysis.

The following variables related to patient background were also used in the multivariate analyses, although they were not significantly related to prognosis: age, sex, virus type, allergy history, flu vaccination record, and acetaminophen use. A history of febrile convolution was excluded because of missing data.

We could not analyze all 442 patients in multivariate analysis because many of the factors with statistical significance in univariate analysis were missing data. A total of 13 of the 16 variables used in multivariate analysis had several missing data points. Thus, a total of 184 patients with complete data were included in multivariate analysis (Fig 1). Reducing the number of cases from 442 to 184 did not significantly alter the percentage of survival and death.

Table 2 summarizes the numbers and percentages of the 184 patients with complete data for these 16 variables and shows the adjusted odds ratios and 95% confidence intervals from multivariate logistic regression analysis. Four significant prognostic factors were used: ASI >500 IU/L ($P = 0.04$), blood glucose <50 mg/dL ($P = 0.04$), hematuria or proteinuria ($P = 0.01$), and the use of diclofenac sodium ($P = 0.03$). The following variables showed a tendency toward being factors for poor prognosis: peak body temperature of 39–40°C ($P = 0.08$), 40–41°C ($P = 0.14$), and $>41^\circ\text{C}$ ($P = 0.05$); platelet $<10 \times 10^9/\mu\text{l}$ ($P = 0.15$); blood glucose >150 mg/dL ($P = 0.14$); fentanyl usage for febrile convulsions ($P = 0.09$); and the use of acetaminophen ($P = 0.06$).

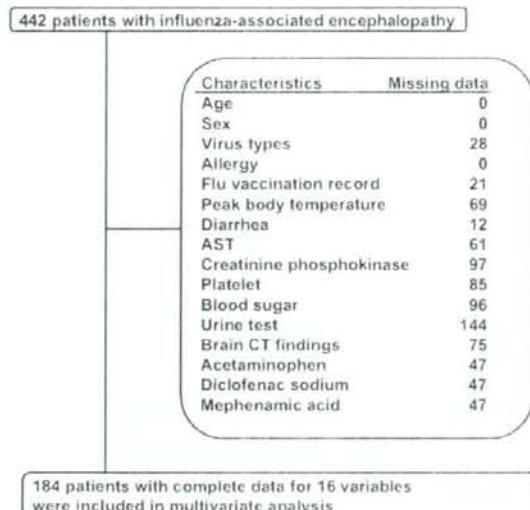

FIGURE 1. Flow chart of patient selection. A total of 442 patients with influenza-associated encephalopathy were reduced to 184 patients because of missing data points in the variables. Variables with missing data are shown with the number of missing data points. AST indicates aspartate aminotransferase; CT, computed tomography.

placed patients with allergies in the good prognosis group in univariate analysis. However, allergy history did not have a significant effect in multivariate analysis, possibly because of control of confounding.

DISCUSSION

An outbreak of encephalopathy suspected to have been caused by influenza infection prompted a national survey of influenza-associated encephalopathy at all hospitals and pediatric clinics in Japan, as well as this analysis of 442 cases. To our knowledge, this is the first study on the prognostic factors of influenza-associated encephalopathy. The mortality rate was as high as 30% without treatment.¹ Therefore, for the administration of intensive care, it is important to identify the factors that affect its prognosis. Using multivariate analysis we identified several factors that were related to the poor prognosis of this disease.

A severely elevated transaminase level, thrombocytopenia, and hematuria or proteinuria were associated with an unfavorable outcome in influenza-associated encephalopathy. Although the pathogenesis of this disease is still unclear, several reports^{1–10} have suggested that it involves cytokines such as soluble tumor necrosis factor receptor I, interleukin-6 (IL-6), IL-8, tumor necrosis factor alpha (TNF- α), IL-10, and IL-10. Neutrophil infiltration in the brain tissue is another characteristic of influenza-associated encephalopathy, probably due to the release of cytokines from activated monocytes and macrophages.^{1,2,11} In addition, the presence of antibodies against the virus in the cerebrospinal fluid has been reported to be associated with a poor prognosis.^{1,2,12} These findings suggest that the pathogenesis of influenza-associated encephalopathy may involve the activation of macrophages and microglia cells by hypercytokinemia.^{1,2} A severely elevated transaminase level, thrombocytopenia, and hematuria or proteinuria may be associated with disseminated intravascular coagulopathy, multiple organ failure, and hemophagocytosis resulting from hypercytokinemia induced by this disease.^{1,3–10}

We also showed that hyperglycemia is a factor leading to poor prognosis. IL-6 may lead to increased cortisol levels, followed by a pronounced dose-dependent increase in blood glucose.^{13–16} Therefore, we postulated that the systemic hypercytokinemia in influenza-associated encephalopathy causes hyperglycemia and that the glucose levels reflect the degree of pathogenicity.

Hypoglycemia provided a significant *P* value of <0.05 in univariate analysis. However, this did not result in a significant difference in the multivariate analysis, which was probably because the number of patients with hypoglycemia in multivariate analysis was reduced from 8 to only 2 cases, or 1.1% of patients, because of missing data. Hypoglycemia is a symptom of Reye syndrome with a very poor prognosis.^{17–19} Medium-chain acyl-CoA dehydrogenase deficiency is the most common disorder of fatty acid β -oxidation, and occurs acutely in Reye's-like syndrome, which is often provoked by infection.¹⁹ Reye's-like syndrome is similar to influenza-associated encephalopathy in several of its symptoms, such as loss of consciousness, seizures, and increased aminotransferase levels.^{1,20} Therefore, we postulated that influenza-associated encephalopathy may include a metabolic disorder, such as medium-chain acyl-CoA dehydrogenase deficiency.

High-grade fever, particularly >41°C, showed a tendency toward being a prognostic factor in the multivariate analysis. Some patients with a poor outcome exhibit a mitochondrial β -oxidation disorder evoked by inactivated carnitine palmitoyltransferase II during high grade fever in influenza-associated encephalopathy.²¹ Analysis of the genotypes and allele compositions of carnitine palmitoyltransferase II have revealed a thermolabile phenotype that occurs more frequently in influenza-associated encephalopathy patients than in healthy subjects.²¹ In addition, the use of the nonsteroidal anti-inflammatory drug diclofenac to alleviate fever affected the prognosis of the disease, and the use of ibuprofen and tended to also influence the prognosis, whereas the use of acetaminophen was considered to have little effect. In May 2001, the Japanese Ministry of Health, Labor and Welfare banned the use of these antipyretic drugs to alleviate fever in influenza infection based on the data of the Collaborative Study Group on Influenza-Associated Encephalopathy.²² However, it is still unclear whether these drugs are related to the pathogenesis of influenza-associated encephalopathy. Shiga-like toxin II or Shiga-like-toxin II-stimulated cytotoxicity may change the brain penetration of diclofenac sodium and mephenamic acid, and consequently increase the risk of the drugs having central nervous system side effects.

We did not find a significant correlation between age and prognosis of encephalopathy, suggesting that age does not affect the outcome of this disease. This finding is consistent with previous reports.^{1,2,12} The mean age of the patients in this study was 10 years old, and the range was 1 month to 18 years old. The mean age of the patients in the study by Nagao et al.¹ was 11 years old, and the range was 1 month to 18 years old. The mean age of the patients in the study by Yamada et al.² was 10 years old, and the range was 1 month to 18 years old.

Values are number of patients. Odds ratios >1 favor survival, odds ratios <1 favor death.

CI, confidence interval.

P* < .05; *P* < .01; ****P* < .001; *****P* < .0001.

The outcome of influenza-related encephalopathy is heterogeneous. The course and pattern of the specific disease in individual children are unpredictable, and often it is difficult to predict the outcome. In our study, 10% of the children had a favorable outcome, 30% had a moderate outcome, and 60% had a poor outcome. The mortality rate was 19%. The overall outcome was favorable in 50% of the children, and the mortality rate was 11%.

We did not obtain information regarding the diagnosis for influenza-associated encephalopathy by age, when we stratified the outcome prior to 1998 (*n* = 60) and 1998 (*n* = 124). In the pre-1998 group, 10% had a favorable outcome, 30% had a moderate outcome, and 60% had a poor outcome. The mortality rate was 17%. The overall outcome was favorable in 50% of the children, and the mortality rate was 11%. In the post-1998 group, 10% had a favorable outcome, 30% had a moderate outcome, and 60% had a poor outcome. The mortality rate was 11%. The overall outcome was favorable in 50% of the children, and the mortality rate was 11%.

and hypothermia therapy were proposed by the Collaborative Study Group on Influenza-Associated Encephalopathy, and further studies to improve influenza-associated encephalopathy prognosis via therapy are currently underway.

In conclusion, we identified several factors related to the poor prognosis of influenza-associated encephalopathy. Use of diclofenac sodium was the causal factor of poor prognosis. The other factors seem to reflect systemic hypercytokinemia, which is thought to play a role in the pathogenesis of the disease. However, all of these factors (with the exception of the use of diclofenac sodium) may be secondary to the disease process because they are seen in subjects who are moribund from a number of causes. Although these factors cannot be used to make an early diagnosis, our results have 2 major implications: the prognostic factors that we identified are easy to examine clinically, and these factors are important for the administration of intensive care in cases of influenza-associated encephalopathy.

日本外来小児科学会予防接種委員会

麻しん及び風しんの定期予防接種の接種体制に関する全国自治体への調査報告

日本外来小児科学会予防接種委員会

藤岡 雅司 永井 崇雄 落合 仁
崎山 弘 田原 卓浩 寺田 喜平
宮崎 千明 横田俊一郎 吉川 哲史

背景

平成17年7月29日に予防接種関連法令が改正され、平成18年4月1日から麻しん及び風しんの定期の予防接種の方法が大幅に変更された。定期接種として使用できるワクチンが弱毒生麻しん風しん混合(以下、MR)ワクチンだけと定められた。そして、定期の予防接種の対象年齢が1歳と就学前年の各々1年間の計2年間に短縮された。また、制度変更に伴う経過措置が設定されなかった。その結果、新制度の下では、一方の接種済み者や罹患者は、もう一方の定期の予防接種を受けられなくなることや、2歳以上の未接種者は就学前まで放置されることなど、法令改正にかかる問題点の指摘が関連学会や関連団体などから相次いだ。結局は、改正法令施行から2か月後の平成18年6月2日に関連法令の再改正が行われ、一部の問題点は解決した。しかし、改正法令が公布されてからの10か月間、定期接種の実務を行う市町村や医療関係者は厚生労働省の対応に翻弄され続けた。

目的

今回の一連の麻しん及び風しんの定期接種に関わる予防接種関連法令の改正によって、定期接種の実施主体である市町村や地区の医師会、小児科医会等は、その対応で混乱した。すなわち、当初の改正法令の公布から施行までの経過と、異例の短期間で法令の再改正が行われたための二重の混乱である。

今回のアンケートは、このような経過の中で、定期接種の実施主体である市町村の対応を調査するために実施した。日本外来小児科学会では一昨年にBCGの制度変更についての全国調査も行った。BCG調査で指摘した問題点も参考に、今回の麻しん及び風しんの定期接種についての一連の混乱の原因も検討した。

方法

全国すべての都道府県及び政令指定都市の予防接種担当課に対しアンケート調査を行った。都道府県に対しては市町村の対応を集計した回答を依頼した。質問の内容は、平成18年8月時点での麻しん及び風しんの

定期予防接種の実施体制（接種方式、接種時期の制限や実費徴収の有無）、未接種者への対応と健康被害への補償体制である。また、今回の法令改正に対する地方自治体の立場での意見も自由記載で依頼した。回答は久留米大学医療センター小児科で回収して集計し、日本外来小児科学会予防接種委員会において結果の分析を行った。

結果

1) 回収率と市町村数の内訳

47都道府県と15政令指定都市の合計62自治体にアンケートを送付し、36府県と14政令指定都市の合計50自治体から回答が得られた。回収率は80.6%であった。平成18年8月1日現在の全国の市町村数は1,819で、集計した市町村の総数は1,310(72.0%)であった。

図1に回答した市町村の内訳を示す。このうち政令指定都市と中核市・特例市を合わせて大規模市、他の市を小規模市、町と村を合わせて町村部とすると、それぞれ49(3.7%)、564(43.1%)、697(53.2%)となつた。残念ながら、今回は東京都から回答が得られなかつたため、特別区は集計に含まれていない。

2) 接種方式について

平成18年度の麻しん及び風しんの定期予防接種の接種方式は、回答のあった1,269市町村の中で、1,120(88.3%)が個別、76(6.0%)が集団、66(5.2%)が個
