

Maestro version 8.5 (Schrödinger, LLC, New York, NY 2007) was used as described below. The crystal coordinates described above were obtained from the Protein Data Bank (<http://www.rcsb.org/>) and used as starting templates. Hydrogens were optimized with constraints on the heavy atoms. The crystal water that mediates the interactions between protease inhibitors and the protease flap was retained, and all other crystal waters were deleted. Close interactions in the protease were annealed, and the docking grid was setup. Polarizable ligand charges were determined at the B3LYP/6-31G* level. The extra-precision mode of Glide,^{29,30} which has a higher penalty for unphysical interactions, was used. For each docking simulation, up to five final poses were retained and compared with available X-ray structures to verify that the conformations were reasonable. It was particularly important that the correct ring conformations were obtained during docking. LPV produced ring conformations that were different than the conformations obtained from crystal complexes in some docking solutions, and such conformations were discarded for the subsequent GBSA simulations.

GBSA Scoring Simulations. The general principle of a GBSA model has been described before. The free energy of binding, ΔG_{bind} is calculated as²

$$\Delta G_{\text{bind}} = \Delta E + \Delta G_{\text{solv}} + \Delta G_{\text{SA}}$$

$$\Delta E = E_{\text{complex}} - E_{\text{protein}} - E_{\text{ligand}}$$

where E_{complex} , E_{protein} , and E_{ligand} are the minimized energies of the protease–inhibitor complex, protease, and inhibitor, respectively.

$$\Delta G_{\text{solv}} = G_{\text{solv}(\text{complex})} - G_{\text{solv}(\text{protein})} - G_{\text{solv}(\text{ligand})}$$

where $G_{\text{solv}(\text{complex})}$, $G_{\text{solv}(\text{protein})}$, and $G_{\text{solv}(\text{ligand})}$ are the solvation free energies of the complex, protein, and inhibitor, respectively.

$$\Delta G_{\text{SA}} = G_{\text{SA}(\text{complex})} - G_{\text{SA}(\text{protein})} - G_{\text{SA}(\text{ligand})}$$

where $G_{\text{SA}(\text{complex})}$, $G_{\text{SA}(\text{protein})}$, and $G_{\text{SA}(\text{ligand})}$ are the surface area energies for the complex, protease, and inhibitor, respectively. The simulations were carried out using the GBSA continuum model³¹ in Prime, version 2.0 (Schrödinger, LLC, New York, NY, 2008). Prime uses a surface-generalized Born (SGB) model employing a Gaussian surface instead of a van der Waals surface for better representation of the solvent-accessible surface area.³¹

GBSA simulations were carried out for the protease–ligand complex structures obtained by molecular docking. The simulations were carried out in four different scenarios. (i) No water molecules were retained in the protease and ligand atoms have fixed charges based on the OPLS force field. This is the standard MM-GBSA simulation carried out in implicit solvation. The change in free energy obtained is denoted by ΔG_{mm} , and the correlation coefficients are denoted by r_{mm} . (ii) No water molecules were retained in the protease and the ligand has protein-polarized QM charges at the B3LYP/6-31G* level. The protein-polarized charge on the ligand is determined from the docked complex and used while computing E_{complex} , $G_{\text{solv}(\text{complex})}$, and $G_{\text{SA}(\text{complex})}$ as well as for E_{ligand} , $G_{\text{solv}(\text{ligand})}$, and $G_{\text{SA}(\text{ligand})}$. The change

in free energy obtained is denoted by ΔG_{qm} , and the correlation coefficients are denoted by r_{qm} . (iii) The bridging water molecule mediating the hydrogen-bond interactions of inhibitors DRV, GRL-98065, APV, GRL-02031, GRL-06579, NFV, SQV, and AZV with Ile50 and Ile50' in the flap was explicitly retained. This is a hybrid solvation model since implicit GBSA solvation terms for the whole system were used. For tipranavir (TPV), GBSA with the hybrid solvation model was performed by retaining a water molecule that bridges hydrogen-bond interactions with Gly48 of one monomer of the protease. NFV and AZV were observed to have two additional bridging water molecules, and additional calculations in the presence of three explicit water molecules were performed for NFV and AZV. In the hybrid solvation model, the inhibitors either had MM charges (change in free energy and correlation coefficient denoted by $\Delta G_{\text{mm/wat}}$ and $r_{\text{mm/wat}}$, respectively) or (iv) protein-polarized QM (B3LYP/6-31G*) charges (change in free energy and correlation coefficient denoted by $\Delta G_{\text{qm/wat}}$ and $r_{\text{qm/wat}}$, respectively). In all simulations, the protease has OPLS charges. The strain energies of the ligands were taken into account.

Antiviral Agents. DRV, GRL-98065, and GRL-02031 were synthesized as described previously.^{32–35} SQV and ritonavir (RTV) were kindly provided by Roche Products Ltd. (Welwyn Garden City, United Kingdom) and Abbott Laboratories (Abbott Park, IL), respectively. APV was a kind gift from Glaxo-Wellcome, Research Triangle Park, NC. NFV and indinavir (IDV) were kindly provided by Japan Energy Inc., Tokyo, Japan. LPV was synthesized by previously published methods.³⁶ AZV was a kind gift from Bristol-Myers Squibb (New York, NY). TPV was obtained through the AIDS Research and Reference Reagent Program, Division of AIDS, NIAID, National Institutes of Health.

Generation of Recombinant HIV-1 Clones. To generate HIV-1 clones carrying desired mutations, site-directed mutagenesis using the QuikChange Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA) was performed, and the mutation-containing genomic fragments were introduced to pHIV-1_{NL₅Ma}, as previously described.^{35,37} Determination of the nucleotide sequences of plasmids confirmed that each clone had the desired mutations but no unintended mutations. Each recombinant plasmid was transfected into 293T cells using Lipofectamine 2000 Transfection Reagent (Invitrogen, Carlsbad, CA), and thus generated infectious virions were harvested 48 h after transfection and stored at -80°C until use. HIV-1 carrying D30N substitution (HIV^{D30N}) was generated since residue-30 is in the active site (Figure 1) and the D30N substitution is known to cause primary drug resistance against the FDA-approved protease inhibitor NFV.³⁸ HIV^{I50V} was generated since Ile50 is in the flap region (Figure 1) and interacts with various PIs through a bridging water molecule.³⁹ The I50V mutation has been associated with resistance to APV, LPV, and RTV.⁴⁰ HIV^{V82I/185V} was also generated since Val82 is located in the active site and its substitution to Ile is associated with HIV-1 resistance to most PIs, presumably due to the expansion of the active site and loss of favorable van der Waals contact.^{15,20,40,41} We recently reported the emergence of I85V as a resistant mutation against a PI, GRL-98065, and chose to study the combined effect of V82A/I85V.³² HIV-1-infected patients who failed to respond to PI-containing regimens often have HIV-1 variants carrying both active site

Figure 1. Structure of dimerized HIV-1 protease. The monomer subunit is shown in a red or green ribbon. The locations of the mutant residue positions are indicated. Only polar hydrogens are shown, and the following atom colors are used in this and all subsequent figures: C, gray; H, white; O, red; N, blue; S, yellow.

and nonactive site mutations in protease, and we chose to explore such clinical HIV-1 isolates, HIV²⁸⁴⁰ and HIV²⁸⁴¹. The former contained L10R, M46I, L63P, V82T, and I84V substitutions, while the latter contained M46I, L63P, V82T, and I84V substitutions.

Drug Susceptibility Assay. To determine the drug susceptibilities of certain laboratory HIV-1 strains, MT-4 cells were employed as target cells, as described previously,³⁷ with minor modifications. In brief, MT-4 cells (10^5 /mL) were exposed to 100 TCID₅₀s of drug-resistant HIV-1 strains in the presence or absence of various concentrations of drugs and incubated at 37 °C. On day 7 of culture, the supernatants were harvested and the amounts of the p24 Gag protein were determined by using a fully automated chemiluminescent enzyme immunoassay system (Lumipulse F; Fujirebio Inc., Tokyo, Japan).⁴² The drug concentrations that suppressed the production of p24 Gag protein by 50% (IC₅₀) were determined by comparison of the amount of p24 Gag protein produced in drug-treated cell cultures with the level of p24 Gag protein produced in a drug-free control cell culture. All assays were performed in duplicate or triplicate on more than three different occasions, and the data are shown as means \pm 1 SD.

RESULTS

Analysis of Water Molecules in Protease Crystal Structures. Since the number of ligand-bound water molecules in high-resolution crystal structures varies widely,⁵ we first analyzed the number of water molecules in the five protease–inhibitor crystal structures used in the current study. The total number of water molecules ranged from 51 (protease–NFV complex,²⁵ PDB ID 1OHR) to 124 (protease–TPV complex,²⁴ PDB ID 2O4P). Within 4 Å of the bound ligand, the number of water molecules present in the complexes with PDB IDs 1HXB, 2FDE, 1OHR, 2O4P, and 2AQU were 3, 5, 5, 10, and 10, respectively. We then analyzed the number of water molecules bridging hydrogen-bond interactions between the protease and the ligands. The water molecule forming

tetracoordinated hydrogen-bond interactions with Ile50 and Ile50' in the flap was the only water molecule interacting with the ligand in the protease complexes of SQV (PDB ID 1HXB), BCV (PDB ID 2FDE), and APV (PDB ID 1HPV⁴³). Since this tetracoordinated water molecule is considered an important pharmacophore for protease–inhibitor interactions,⁴⁴ it was explicitly included in our docking and GBSA free energy simulations. Three water molecules formed bridging hydrogen-bond interactions in the NFV–protease (PDB ID 1OHR) and AZV–protease (PDB ID 2AQU) complexes (Figure 2c and 2q), and simulations were carried out with both one and three bridging water molecules explicitly present for these inhibitors. TPV directly formed hydrogen bonding with Ile50 and Ile50', and a water molecule bridged hydrogen bonding with Gly48 in the flap (Figure 2g)^{24,45,46} and was explicitly included in the simulations. Simulations involving LPV did not include any crystal waters since none were present in the native LPV–protease complex.²⁶

Determination of the Susceptibility of Recombinant Infectious HIV-1 Clones Carrying Amino Acid Substitutions to PIs in Vitro. We determined the susceptibility of six recombinant infectious HIV-1 clones to each of the PIs that were chosen in the present study: 7 clinically available PIs (SQV, NFV, APV, TPV, DRV, and AZV) and 2 experimental PIs (GRL-02031 and GRL-98065) in the HIV-1 p24 Gag production inhibition assay, as previously described.^{35,37} As illustrated in Table 1, most of the recombinant clones showed reduced susceptibility to the PIs examined by up to 16.5-fold. However, it was also noted that HIV^{D30N} and HIV²⁸⁴¹ had increased susceptibility to certain PIs. The increased susceptibility of HIV^{D30N} to TPV with 33.3-fold was notable, although HIV^{D30N} was also less susceptible to SQV, LPV, and NFV (Table 1). Both HIV^{I50V} and HIV²⁸⁴⁰ were also less susceptible to most of the PIs (Table 1).

Binding Interactions with Wild-Type and D30N Mutant Protease. We next determined and analyzed the binding modes of nine different PIs with PRO^{WT} and a protease with an amino acid substitution at position 30 from an aspartic acid to asparagine (PRO^{D30N}). SQV has four hydrogen-bond interactions with Asp29 and Asp30 in the S2 site of the wild-type protease but has no hydrogen bonds with Asp29' or Asp30' in the S2' site (Figure 2a). When protease acquires the D30N mutation, SQV loses two hydrogen bonds with Asp29 and Asp30 and does not form any new and compensating hydrogen bonds with other protease residues (Figure 2b). Comparison of the antiviral data of SQV shown in Table 1 indicates that there was a 3.9-fold decrease in antiviral potency with the D30N mutation. It is possible that the decrease of antiviral potency of SQV for D30N mutant is due to the loss of hydrogen bonds with residues 29 and 30 for the mutant. Examining the hydrogen bonds in the S2 site for NFV against PRO^{WT} and PRO^{D30N} mutant protease (Figure 2c and 2d), one observes that NFV has more hydrogen bonds with Asn30 of PRO^{D30N} compared to Asp30 of PRO^{WT}. An X-ray crystal structure has also demonstrated that NFV has a larger number of hydrogen bonds with PRO^{D30N} than with PRO^{WT}.¹¹

However, D30N is a major amino acid substitution³⁸ associated with NFV resistance of HIV-1, and HIV^{D30N} showed a 5.3-fold increase in IC₅₀ values in antiviral assays

Figure 2. Interactions of protease inhibitors with wild-type and D30N mutant protease. Interactions of SQV with (a) wild-type (PRO^{WT}) and (b) D30N-containing mutant protease (PRO^{D30N}) are shown. SQV has hydrogen-bond interactions (dotted yellow lines) only in the S2 site but no such interactions in the S2' site. The hydrogen bonds of SQV with the mediating water molecule, Asp25, Asp25', and Gly27, are present but not shown. Hydrogen-bond interactions of NFV with (c) PRO^{WT} and (d) PRO^{D30N} . The bridging water-303 has hydrogen bonds with Ile50 and Ile50', water-315 hydrogen bonds with Asp29', and water-422 hydrogen bonds with Gly27'. Simulations were carried out for NFV with these three water molecules explicitly present, with one of the bridging water molecules and without any explicit water molecule. Nefinavir has more hydrogen bonds with residues 29 and 30 in PRO^{D30N} even though it has a lower antiviral potency against HIV-1^{D30N}. Hydrogen bonds of LPV with (e) PRO^{WT} and (f) PRO^{D30N} . LPV has more hydrogen-bond interactions with the S2 site for the mutant than it has for the PRO^{WT} . The crystal structure for LPV 1MUI (PDB ID) does not have waters. Hydrogen-bond interaction of TPV with (g) PRO^{WT} and (h) PRO^{D30N} . Unlike other inhibitors in this study, TPV directly hydrogen bonds with Ile50 and Ile50' but a bridging water molecule hydrogen bonds with Gly48 in the flap. Interactions of APV with (i) PRO^{WT} and (j) PRO^{D30N} are shown. In the S2 site of the protease, the THF ligand of APV has an additional hydrogen bond with Asn30 (PRO^{MT}) compared to Asp30 (PRO^{WT}). In the S2' site, the aniline nitrogen of APV has a hydrogen bond with the side chain of Asp30 (PRO^{WT}) and the hydrogen bond is lost for the Asn30 mutant. Structural interaction of DRV with (k) PRO^{WT} and (l) PRO^{D30N} are shown. The bis-THF ligand of DRV has more hydrogen-bond interactions with PRO^{D30N} compared to the PRO^{WT} . The water molecule mediating hydrogen bonds between the inhibitor and Ile50 and Ile50' in the flap is shown. The water molecule is present in docking and free energy simulations of APV, GRL-98065, GRL-02031, and SQV but is not shown. Hydrogen-bond interactions of GRL-02031 with (m) PRO^{WT} and (n) PRO^{D30N} are shown. (o) Hydrogen-bond interactions of GRL-98065 with wild-type protease are shown. The bis-THF ligand of GRL-98065 has hydrogen-bond interactions with backbone atoms of Asp29 and Asp30 in the S2 site and with Asp30' in S2'. (p) Besides maintaining the backbone hydrogen bonds with Asp29 and residue-30 and -30' of PRO^{D30N} , GRL-98065 forms additional hydrogen bonds with the side chains of Asn30 and Asn30'. Hydrogen-bond interactions of AZV with (q) PRO^{WT} and (r) PRO^{D30N} .

^a The IC_{50} values shown represent means ± 1 SD of assays conducted in duplicate or triplicate on more than three different occasions for the study. ^b The fold change in activity of the mutants from the wild-type IC_{50} are shown within brackets.

(Table 1). Examining the structural interactions of LPV and TPV against PRO^{WT} and PRO^{D30N} mutants (Figure 2e–h), we observed that both inhibitors have more hydrogen bonds with residues 29 and 30 of PRO^{D30N} than they have for those of PRO^{WT} . Antiviral data show that while LPV has a 3.1-fold increase in IC_{50} , HIV^{D30N} was about 30 times more sensitive to TPV (Table 1). Comparison of the structural interactions of DRV, TPV, GRL-02031, and GRL-98065 with PRO^{WT} and PRO^{D30N} (Figure 2k–p) revealed that all of them have more hydrogen-bond interactions with PRO^{D30N} . APV, which is 5-fold more potent against HIV^{D30N} (Table 1), has three hydrogen bonds with Asp29, Asp30, and Asp30' for PRO^{WT} and forms three hydrogen bonds with Asp29 and Asn30 for PRO^{D30N} in structural models (Figure 2i and 2j). Thus, it is clear that while the number of hydrogen bonds may provide an intuitive understanding of binding and/or antiviral potency, it may not always explain why certain

PIs show a decrease in antiviral potency with D30N substitution while other PIs show an increase.

Free Energy Changes in Complexes with the D30N Mutation Determined by GBSA Simulations. Since the number of hydrogen bonds between PIs and protease does not always help predict the potency of PIs as discussed above, we examined the free energies under four different simulation conditions: with and without explicit water(s) and with QM or with MM charges on the inhibitor (Table 2, Supporting Information Tables S1 and S2). It was assumed that an increase in the change of free energy of binding ($\Delta\Delta G$ more positive) is to be expected for a decrease in antiviral activity and vice versa. With the D30N mutation in PRO^{D30N} , SQV showed a reduction in antiviral activity by 3.9-fold. With the bridging water and QM charges on SQV, the free energy change ($\Delta\Delta G_{\text{qm/wat}}$) of the SQV–protease complex increased by 4 kcal/mol for the D30N mutation (Table 2). HIV^{D30N}

Table 2. Change in Free Energy (kcal/mol) Associated with D30N Mutation^a

inhibitor	$\Delta\Delta G_{\text{qm/wat}}$ (kcal/mol)	$\Delta\Delta G_{\text{mm/wat}}$ (kcal/mol)	$\Delta\Delta G_{\text{qm}}$ (kcal/mol)	$\Delta\Delta G_{\text{mm}}$ (kcal/mol)	IC ₅₀ fold change ^b
saquinavir	+4	+4	-1	-2	3.9
nelfinavir	+7	+9	-11	-9	5.3
lopinavir	n.d.	n.d.	+17	+21	3.1
amprenavir	-12	+12	+11	+7	0.2
tipranavir	-5	-2	-12	-9	0.03

^a The qm subscript refers to the use of protein-polarized QM charges on the inhibitor, and the mm subscript refers to the use of fixed force-field-based charges. The use of an explicit bridging water is shown by the wat subscript. A positive $\Delta\Delta G$ indicates a decrease in binding affinity, while a negative $\Delta\Delta G$ indicates an increase. ^b IC₅₀ fold change greater than 1 indicates a reduction in potency with D30N mutation, while a fold change of less than 1 indicates sensitivity.

AZV	0.76	0.54	0.91^b	0.64^b	0.13	0.14	0.34 ^b	0.53^b	0.24	0.17	0.62^b	0.58^b

^a The qm subscript refers to the use of protein-polarized QM charges on the inhibitor, and the mm subscript refers to the use of fixed force-field-based charges. The use of an explicit bridging water is shown by the wat subscript. Bold font indicates correlation (*r* > 0.5). ^b Calculated with three water molecules that mediate hydrogen bonds between the protease and the inhibitor.

was resistant to NFV by 5.3-fold compared to HIV^{WT}, and $\Delta\Delta G_{\text{qm/wat}}$ showed an increase in the free energy of binding by +7 kcal/mol. HIV-1 containing PRO^{D30N} was more sensitive to APV and TPV, and $\Delta\Delta G_{\text{qm/wat}}$ for PRO^{D30N} with APV and TPV was -12 and -5 kcal/mol, respectively (Table 2). The $\Delta\Delta G_{\text{qm/wat}}$ values showed that both TPV and APV had a higher affinity for PRO^{D30N} than for PRO^{WT} (Table 2) and correlated with the increase in sensitivity to these inhibitors.

We next compared the free energy changes ($\Delta\Delta G_{\text{mm/wat}}$) simulated using the bridging water molecule but with force-field-based fixed MM charges on the inhibitors. The $\Delta\Delta G_{\text{mm/wat}}$ values of +4 and +9 kcal/mol for SQV and NFV, respectively, showed that the simulation results in an increase in the free energy of binding correlating with the reduction of antiviral activity. However, the $\Delta\Delta G_{\text{mm/wat}}$ value showed a wrong trend for APV (+12 kcal/mol) and was alike for TPV (-2 kcal/mol). The $\Delta\Delta G_{\text{qm}}$ and $\Delta\Delta G_{\text{mm}}$ values were negative for SQV and NFV, respectively, while they were positive for APV. Thus, $\Delta\Delta G_{\text{qm}}$ and $\Delta\Delta G_{\text{mm}}$ values, which did not incorporate the bridging water molecule explicitly, simulated inaccurate changes in the free energy of binding for SQV, NFV, and APV. The crystal structure for LPV (PDB ID 1MUI) did not have any water molecules present, and all simulations involving LPV were carried out with implicit water. The $\Delta\Delta G_{\text{qm}}$ and $\Delta\Delta G_{\text{mm}}$ values for LPV were +17 and +21 kcal/mol, respectively. The increase in the change in the free energy of binding of LPV with PRO^{D30N} was consistent with its decrease in antiviral potency with D30N substitution. For TPV, the negative $\Delta\Delta G_{\text{qm}}$ and $\Delta\Delta G_{\text{mm}}$ values indicated favorable free energy of binding

for PRO^{D30N} compared to PRO^{WT} and correlated with the increase in antiviral potency of TPV with the D30N mutant.

In summary, the $\Delta\Delta G_{\text{qm/wat}}$ values provided consistent trends of the change in free energy of binding for PRO^{D30N}, which is resistant to SQV and NFV but is more sensitive to APV and TPV. $\Delta\Delta G_{\text{qm}}$ and $\Delta\Delta G_{\text{mm}}$ did not always provide the correct trend of change in the free energies of binding.

Correlation of Free Energy and Antiviral Potency for Active Site Mutants. The GBSA free energies were simulated under four conditions: (i) with implicit solvation terms and MM charges on both ligand and protein (ΔG_{mm}), (ii) with explicit water and implicit solvation terms (hybrid solvation model) with MM charges on both ligand and protein ($\Delta G_{\text{mm/wat}}$), (iii) with implicit solvation terms and protein-polarized QM charges on the ligand and MM charges on the protein (ΔG_{qm}), and (iv) with explicit water and implicit solvation terms (hybrid solvation model) with QM charges on the ligand and MM charges on the protein ($\Delta G_{\text{qm/wat}}$). All the free energy values determined are shown in Supporting Information Tables S1 and S2.

We analyzed the correlation of the free energies thus computed with the experimentally determined antiviral potency data (IC₅₀), and the resultant correlation coefficients are shown in Table 3, where Set-1 refers to the correlation coefficient for PRO^{WT}, PRO^{D30N}, and PRO^{I50V}, Set-2 refers to the correlation coefficient for PRO^{WT}, PRO^{D30N}, PRO^{I50V}, and PRO^{V82I/185V}, and Set-3 refers to the correlation coefficients for PRO^{WT}, PRO^{D30N}, PRO^{I50V}, PRO^{V82I/185V}, PRO^{284Q}, and PRO^{284I}. For Set-1, *r*_{mm} (correlation coefficient of ΔG_{mm} vs IC₅₀) showed a strong correlation for only TPV, LPV, and AZV (Table 3). The *r*_{mm} value was poor for the other PIs and indicates the difficulty of obtaining reasonable

correlations between free energies and antiviral potency. The r_{qm} (correlation coefficient of ΔG_{qm} vs IC_{50}) values that represented correlation coefficients when the free energies were simulated with polarized QM charges on the ligands showed significant improvement and a strong correlation for DRV, APV, GRL-02031, and LPV. However, both r_{mm} and r_{qm} values were poor for GRL-98065 and SQV.

We next determined, for Set-1, the correlation obtained by the hybrid water model that has an explicit bridging water molecule between the inhibitor and the protease flap. The explicit water was treated as a part of the protein, and implicit solvation terms were used. The $r_{mm/wat}$ value (correlation coefficient of $\Delta G_{mm/wat}$ vs IC_{50}) represented a greater correlation than r_{mm} for all PIs except TPV and AZV. TPV directly formed hydrogen bonds with Ile50 and Ile50', and the water molecule included in this calculation formed hydrogen bonds with Gly48 of one monomer of the protease dimer. For other PIs, the bridging water molecule formed hydrogen bonds with the flaps from both monomers. The $r_{qm/wat}$ value (correlation coefficient of $\Delta G_{qm/wat}$ vs IC_{50}) had a high degree of correlation for all PIs except AZV. Thus, the explicit inclusion of the water molecule bridging hydrogen bonds with the flap and protein-polarized QM charges for the inhibitors provided strong correlation ($r > 0.75$) for seven out of eight inhibitors. The correlation coefficient $r_{qm/wat}$ for NFV with three bridging waters was 0.97, a significant improvement over the correlation coefficient of 0.77 obtained with one bridging water molecule. The $r_{qm/wat}$ value for AZV also improved from 0.16 to 0.64 with the inclusion of three bridging water molecules.

We also determined r_{mm} , r_{qm} , $r_{mm/wat}$, and $r_{qm/wat}$ values for Set-2, which included PRO^{V82I/I85V} as well (Table 3). The r_{mm} value was poor for all PIs except TPV, while the r_{qm} values showed good correlations for DRV, LPV, and TPV. The $r_{mm/wat}$ value showed strong correlation for only SQV and good correlation ($0.55 < r < 0.75$) for NFV. The $r_{qm/wat}$ value showed strong correlations for DRV, APV, and SQV and good correlations for GRL-98065 and TPV. The $r_{qm/wat}$ value for NFV jumped from 0.59 to 0.92 with the incorporation of three bridging water molecules instead of one.

The correlation coefficients with a hybrid water model and with QM-polarized ligand charges ($r_{qm/wat}$) on the PIs were higher for most of the PIs compared to the correlation coefficients obtained without any explicit water molecule and MM charges (r_{mm}). The only exception was for TPV, which was the only nonpeptidomimetic inhibitor among the PIs examined. TPV displaces the tetracoordinated water molecule and interacts directly with Ile50 and Ile50' in the flap.⁴⁶ The hydrogen-bond interaction of the bridging water molecule with TPV and Gly48 of one chain might not be an important contributor to its potency. Also, in general, the $r_{qm/wat}$ values provided better correlations than r_{qm} .

Correlation of Free Energy and Antiviral Potency for Active and Nonactive Site Amino Acid Substitutions. We next analyzed the correlations of the free energies with the antiviral potency (IC_{50} values) for PRO^{WT}, PRO^{D30N}, PRO^{I50V}, PRO^{V82I/I85V}, PRO²⁸⁴⁰ that contains L10R, M46I, L63P, V82T, and I84V, and PRO²⁸⁴¹ that contains M46I, L63P, V82T, and I84V substitutions (Set-3 in Table 3). The analysis of PRO²⁸⁴⁰ and PRO²⁸⁴¹ was substantially complex since both proteases contained nonactive site substitutions, but it was worth examining the ability of the

Figure 3. Correlation of free energy and antiviral activity. (a) Scatter plot of $\Delta G_{qm/wat}$ vs pIC_{50} for DRV for Set-3. (b) Scatter plot of $\Delta G_{qm/wat}$ vs pIC_{50} (PRO^{WT}) for ligands with bis-THF-related cores. The correlation coefficient is shown in both figures.

GBSA energy function to correlate with antiviral activity when substitutions distant from the inhibitor were present. In general, the correlation coefficients for Set-3 turned out to be low, indicating a lower correlation between the free energies and antiviral potencies when nonactive site mutants were present. For DRV, the r_{mm} , r_{qm} , and $r_{mm/wat}$ values indicated that the corresponding free energies had no correlation with IC_{50} values. However, the value of $r_{qm/wat}$ for DRV was 0.83, showing a strong correlation for simulations with polarized QM charges on the inhibitor with a hybrid water model (Table 3, Figure 3a). For SQV, strong correlations were obtained for both ΔG_{mm} with IC_{50} ($r_{mm} = 0.78$) and $\Delta G_{qm/wat}$ with IC_{50} ($r_{qm/wat} = 0.84$). For APV and TPV, $r_{qm/wat}$ values were 0.60 and 0.50, respectively, but there was no correlation when other GBSA protocols were used for these inhibitors. The $r_{qm/wat}$ values were greater than 0.75 for two inhibitors and greater than 0.55 for five inhibitors. The r_{qm} and $r_{mm/wat}$ values were greater than 0.55 for two inhibitors. Thus, the hybrid water model and inclusion of polarization effects, compared to the other protocols, simulated free energies with better correlation with antiviral IC_{50} for more inhibitors.

GBSA with Hybrid Water Model and Polarizable Quantum Charges on PIs as a Lead Optimization Tool. Obtaining a correct relative rank of activity for inhibitors that had potency in the nanomolar range has been a real challenge for scoring methods.³ Scoring methods providing sufficiently high correlation with potency may serve as a lead optimization tool. In our data set, DRV and GRL-98065 have a bis-THF group as the core, GRL-06579 and GRL-02031 have a Cp-THF as the core, and APV has a THF group as the core. All these inhibitors were extremely potent against PRO^{WT} and had a narrow range of activity

Table 4. Experimental Free Energies^a of Protease Inhibitors Against PRO^{WT}

	DRV	APV	GRL-98065	GRL-02031	GRL-06579
IC ₅₀ (μ M)	0.003	0.028	0.0003	0.02	0.002
ΔG_{exp} (kcal/mol)	-11.6	-10.3	-13.0	-10.5	-11.9

^a Experimental free energies determined as $\Delta G_{\text{exp}} = RT \ln(\text{IC}_{50})$, where R and T represent the universal gas constant and temperature, respectively.

ranging from 0.3 to 28 nM (Table 1). We computed ΔG_{exp} from the antiviral IC₅₀ values (Table 4). Such transformations have recently enhanced the understanding of the binding of *N*-sulphonyl-glutamic acid inhibitors to MurD ligase and in understanding the efficiency of DNA catalysis.^{19,47} Substitution of the THF group of APV with the bis-THF group (DRV) resulted in a -1.3 kcal/mol improvement in the free energy of binding. GRL-98065 has a 1,3-benzodioxole group as P2' ligand compared to an aniline group in DRV, which resulted in the ΔG_{exp} of GRL-98065 being lower (i.e., better binding affinity) by -1.4 kcal/mol than DRV. Both GRL-06579 and GRL-02031 have a Cp-THF as the P2 ligand but different substituents interacting with the S1' and S2' locations in the protease active site. The ΔG_{exp} of GRL-06579 is lower by 1.4 kcal/mol than GRL-02031. Among these five PIs, APV and GRL-02031 have the worst ΔG_{exp} and GRL-98065 has the best ΔG_{exp} . The absolute magnitudes of our simulated GBSA free energies are larger than those measured experimentally due to the force-field parameters and the form of the energy function, but trends and correlation with experiments can be deduced. Our $\Delta G_{\text{qm/wat}}$ values simulated the correct trend by predicting that the worst binding free energy was for APV and GRL-02031, and the best binding free energy was for GRL-98065 (Supporting Information Table S1). None of the other GBSA protocols predicted the trend correctly (Supporting Information Tables S1 and S2). We further analyzed the correlation of the free energies calculated by our methods against IC₅₀ values for these five PIs. The r_{mm} and $r_{\text{mm/wat}}$ values were 0.10 and 0.03, respectively, indicating that there was no correlation of GBSA free energies simulated by using MM charges with or without explicit inclusion of water. The difficulty of obtaining good correlation of free energies against antiviral activity is evident from this small but nontrivial data set. The r_{qm} value was 0.74, indicating that incorporation of protein-polarized QM charges on the inhibitors substantially improved the correlation. Including the bridging water molecule with protein-polarized QM charges on the PIs resulted in a $r_{\text{qm/wat}}$ value of 0.93 for PRO^{WT} (Figure 3b). Thus, a simulation using the hybrid water model and protein-polarized QM charges on the ligands resulted in a strong correlation, while there was no correlation for simulations with fixed MM charges.

For our docking and subsequent GBSA simulations, we used the crystal coordinates of BCV-protease complex (PDB ID 2FDE)²² as our starting template. BCV, DRV, and GRL-98065 had a bis-THF moiety as the core ligand, and APV, GRL-06579, and GRL-02031 had cores that had a high similarity with bis-THF. The high correlation obtained with $\Delta G_{\text{qm/wat}}$ -IC₅₀ indicated that free energies obtained with a hybrid water model and polarized QM charges on the ligands would be a promising approach for lead optimization. Currently, we are exploring the utility of GBSA free energy simulations once a correct binding mode is obtained, and

we wanted to use native or native-like crystal structure as a template as a proof-of-principle study. We have not explored docking ligands against non-native protease crystal structures in the current study. A more exhaustive examination that includes poses obtained by cross docking needs to be performed.

DISCUSSION

Progress has been made in improving the robustness of scoring functions to determine the relative affinity of inhibitors for target proteins, but there are vast scopes where significant improvement can be made.^{1,3} Part of the reason for the inaccuracies in the scoring functions arise because (i) the current methodologies largely account for enthalpic changes while completely ignoring entropic changes, (ii) they do not properly treat protein flexibility, (iii) they do not properly account for solvation and desolvation effects, and (iv) they do not account for the polarization induced by the protein and the ligand on each other.^{1,3,7} Most of the studies on scoring functions deal with rank ordering the activity of a congeneric set of ligands. The prediction of activity of a ligand against mutant proteins is very important in light of drug-resistance mutations that emerge in many therapeutic areas.

We explored the correlation of GBSA free energies with antiviral potency (IC₅₀ values) of nine different PIs against wild-type and mutant proteases. Correlation with enzymatic K_i would result in similar conclusions since these PIs have good cell penetration and are highly protease-specific inhibitors. Furthermore, these PIs do not form aggregates and do not have the problematic properties discussed by Shoichet et al.^{48,49}

The GBSA free energies were simulated by four different protocols: (i) fixed MM charges in implicit solvent (ΔG_{mm}), (ii) protein-polarized QM charges of PIs in implicit solvent (ΔG_{qm}), (iii) fixed MM charges in a hybrid solvent ($\Delta G_{\text{mm/wat}}$), and (iv) protein-polarized QM charges of PIs in a hybrid solvent ($\Delta G_{\text{qm/wat}}$). The hybrid solvent protocols have retained an explicit water molecule(s) that bridges hydrogen bonding with the protease in an otherwise implicit solvent environment. The protein-polarized ligand charges were determined during ligand docking in the protein environment at the B3LYP/6-31G* level, and these polarized charges were maintained for the ligand for the full GBSA simulation cycle. These enable us to analyze the effect of a different charge model compared to the static charges from a force field (Supporting Information Figures S3 and S4). Free energies from a successful GBSA protocol should provide a good correlation with the antiviral activity against wild-type and mutant protease. Resistance mutations in the protease active site arise primarily due to loss of favorable binding interactions. Resistance caused by nonactive site mutations is more difficult to understand and rationalize,

although some attempts to elucidate the mechanism have recently been made.^{12,50–52}

We initially compared the correlation coefficients for PRO^{WT}, PRO^{D30N}, and PRO^{I50V} (Set-1). The antiviral potency of the inhibitors for wild-type and mutant proteases are shown in Table 1, and the inhibitors have potency (IC₅₀ values) in the nanomolar range. The $r_{\text{qm/wat}}$ value was higher than 0.75 for 7 out of 8 PIs for Set-1, with $r_{\text{qm/wat}}$ being more than 0.90 for 4 PIs (Table 3). PRO^{D30N} was associated with SQV, NFV, and LPV resistance of HIV-1 and increased susceptibility to APV and TPV (Table 1). It is noteworthy that $r_{\text{qm/wat}}$ showed substantial correlation values of greater than 0.75 even though the fold change in antiviral activity for PRO^{D30N} is nonmonotonic. AZV is the only PI that did not show a correlation of $\Delta G_{\text{qm/wat}}$ with the IC₅₀ value with one bridging water molecule. By including two additional bridging water molecules for NFV and AZV, $r_{\text{qm/wat}}$ improved to 0.97 and 0.64, respectively. Selective inclusion of explicit water molecules needs to be explored and validated. For Set-1, $r_{\text{mm/wat}}$, r_{qm} , and r_{mm} had strong correlation for 4, 3, and 3 PIs, respectively.

Correlations for Set-2 included the mutant PRO^{V82I/I85V}. While V82I is located in the protease active site and represents one of the major resistance-associated mutations for PIs, I85V was selected as a resistance-associated mutation for GRL-98065 even though it does not form a direct van der Waals contact.³² For Set-2, the number of PIs that showed strong correlation coefficients for $r_{\text{qm/wat}}$ and $r_{\text{mm/wat}}$ were 4 and 1, respectively, while r_{qm} and r_{mm} did not show strong correlations for any PI. Set-3 included Set-2 as well as PRO²⁸⁴⁰ and PRO²⁸⁴¹, which had mutations distant from the active site. We included such mutations because they are seen in drug-resistant HIV-1-harboring patients, and we wanted to test the ability of the GBSA energy function to correlate with the antiviral IC₅₀ for such protease substitutions. The $r_{\text{qm/wat}}$ values showed strong correlation coefficients for only DRV and SQV for Set-3 and moderate correlation for 3 other PIs. The correlation coefficients, $r_{\text{mm/wat}}$ and r_{qm} , were from 0.55 to 0.75 for two PIs in Set-3, suggesting that those two PIs had a moderate correlation between the free energies and the IC₅₀ values.

Analysis of correlation coefficients in Table 3 indicated that $r_{\text{qm/wat}}$ had strong ($r > 0.75$) and moderate ($0.55 < r < 0.75$) correlation for more PIs than $r_{\text{mm/wat}}$, r_{qm} , or r_{mm} . This suggested that the GBSA free energies simulated with a hybrid water model with protein-polarized QM charges on the inhibitors had a higher correlation with antiviral IC₅₀ than the other free energy simulation protocols. Others^{1,3} have suggested that improved treatment of solvation and polarizability may improve the robustness of scoring functions, and we demonstrated that our use of selected explicit water molecule(s) and protein-polarized QM partial charges on the inhibitor provided greater correlation with antiviral potency. Further improvement might be achieved by (i) improving upon the hybrid water model (ii) by accounting for the polarization induced by the inhibitors on the protein atoms and (iii) by including changes in entropy.

ACKNOWLEDGMENT

This work was supported in part by the Intramural Research Program of the Center for Cancer Research,

Nucleoside reverse transcriptase inhibitors (NRTIs) are employed in first line therapies for the treatment of human immunodeficiency virus (HIV) infection. They generally lack a 3'-hydroxyl group, and thus when incorporated into the nascent DNA they prevent further elongation. In this report we show that 4'-ethynyl-2-fluoro-2'-deoxyadenosine (EFdA), a nucleoside analog that retains a 3'-hydroxyl moiety, inhibited HIV-1 replication in activated peripheral blood mononuclear cells with an EC₅₀ of 0.05 nM, a potency several orders of magnitude better than any of the current clinically used NRTIs. This exceptional antiviral activity stems in part from a mechanism of action that is different from approved NRTIs. Reverse transcriptase (RT) can use EFdA-5'-triphosphate (EFdA-TP) as a substrate more efficiently than the natural substrate, dATP. Importantly, despite the presence of a 3'-hydroxyl, the incorporated EFdA monophosphate (EFdA-MP) acted mainly as a *de facto* terminator of further RT-catalyzed DNA synthesis because of the difficulty of RT translocation on the nucleic acid primer possessing 3'-terminal EFdA-MP. EFdA-TP is thus a translocation-defective RT inhibitor (TDRTI). This diminished translocation kept the primer 3'-terminal EFdA-MP ideally located to undergo phosphorolytic excision. However, net phosphorolysis was not substantially increased, because of the apparently facile reincorporation of the newly excised EFdA-TP. Our molecular modeling studies suggest that the 4'-ethynyl fits into a hydrophobic pocket defined by RT residues Ala-114, Tyr-115, Phe-160, and Met-184 and the aliphatic chain of Asp-185. These interactions, which contribute to both enhanced RT utilization of EFdA-TP and difficulty in the translocation of 3'-terminal EFdA-MP primers, underlie the mechanism of action of this potent antiviral nucleoside.

Nucleoside reverse transcriptase inhibitors (NRTIs)⁴ are central components of first line regimens for treatment of HIV infections (1–6). Currently, there are eight clinically approved NRTIs: AZT, 3TC, FTC, ABC, ddI, ddC, d4T, and the nucleotide tenofovir (TFV; reviewed in Refs. 7 and 8). A structural hallmark of these NRTIs is the lack of a 3'-OH; it has long been considered that the absence of the 3'-OH is essential for antiviral activity. However, the absence of the 3'-OH in NRTIs also imparts detrimental properties to the inhibitor, including reduced affinity for RT compared with the analogous dNTP substrate, as well as reduced intracellular conversion to the active nucleoside triphosphate (9).

Previously we described a series of 4'-substituted NRTIs (10) that retain the 3'-OH group and have excellent antiviral properties and significantly improved selectivity indices (CC₅₀/EC₅₀) compared with the approved NRTIs. Furthermore, these NRTIs efficiently suppress various NRTI-resistant HIV. The most potent of these 4'-substituted NRTIs are the adenosine analogs that have an ethynyl group at the 4' position of the ribose ring. Despite their high anti-HIV activity, 4'-substituted compounds are susceptible to degradation by adenosine deaminase (11), a property that limits the plasma and intracellular half-life of the drugs. To overcome the adenosine deaminase sensitivity of these 4'-ethynyl NRTIs, we developed a second generation of analogs substituted at the 2-position of the adenine ring (12). We recently reported that the 2-halogenated, 4'-ethynyl compounds have remarkably improved potency and selectivity indices (CC₅₀/EC₅₀) compared with the nonhalogenated analogs and significantly better ones compared with

other approved NRTIs. These compounds are resistant to degradation by adenosine deamination (13). The most potent of these compounds is EFdA (Fig. 1A), which was recently shown not to inhibit human DNA polymerases α and β or mitochondrial DNA polymerase γ (12). Notably, clinically important drug-resistant HIVs (14, 15) are sensitive or hypersensitive to this compound (13).

Despite its remarkable antiviral potency, the molecular mechanism by which EFdA and related compounds inhibit HIV is unknown. To elucidate this mechanism we carried out biochemical experiments that systematically decipher the effect of EFdA on each of the mechanistic steps of DNA synthesis by HIV RT. On the basis of these experiments we propose that EFdA-5'-triphosphate (EFdA-TP) inhibits RT by first being incorporated at the 3'-primer terminus, and after its incorporation it prevents further addition of nucleotides by blocking the translocation of the primer strand on the viral polymerase. We therefore termed EFdA a "translocation-defective reverse transcriptase inhibitor (TDRTI)." By understanding the molecular details of RT inhibition by a highly potent NRTI, we hope to gain insights into the design of even more efficacious inhibitors that may act via same or similar mechanisms.

EXPERIMENTAL PROCEDURES

Enzymes and Nucleic Acids

The RT genes coding for p66 and p51 subunits of BH10 HIV-1 were cloned in the pETDuet-1 vector (Novagen) using restriction sites NcoI and SacI for the p51 subunit and SacII and AvrII for the p66 subunit. The sequences coding for a hexahistidine tag and the 3C protease recognition sequence were added at the N terminus of the p51 subunit. RT was expressed in BL21 (Invitrogen) and purified by nickel affinity chromatography and MonoQ anion exchange chromatography (16). Oligonucleotides used in this study were synthesized chemically and purchased from Integrated DNA Technologies (Coralville, IA). Sequences of the DNA/RNA substrates are shown in Table 1. Deoxynucleotide triphosphates and dideoxynucleotide triphosphates were purchased from Fermentas (Glen Burnie, MD). EFdA was synthesized by Yamasa Corp. (Chiba, Japan) as described previously (12). Using EFdA as the starting material, the triphosphate form, EFdA-TP, was synthesized by TriLink BioTechnologies (San Diego, CA). Concentrations of nucleotides and EFdA-TP were calculated spectrophotometrically on the basis of absorption at 260 nm and their extinction coeffi-

cients. All nucleotides were treated with inorganic pyrophosphatase (Roche Diagnostics) as described previously (17) to remove traces of PP_i contamination that might interfere with the rescue assay.

Cell-based HIV-1 Replication Assays

Peripheral blood mononuclear cells (PBMCs) were isolated from healthy donor buffy coats (purchased from the Central Blood Bank, Pittsburgh, PA) using Ficoll-Hypaque (Histopaque, Sigma-Aldrich) gradient centrifugation as described previously (18). PBMCs were stimulated with 5 μ g/ml phytohemagglutinin (Sigma) in RPMI 1640 containing 10% fetal bovine serum for 48 h prior to exposure to drug and virus. After washing, the activated cells were resuspended in RPMI 1640/fetal bovine serum containing interleukin-2 (10 units/ml) and varying concentrations of the NRTIs and then were infected with HIV-1_{NL4-3} at a multiplicity of infection of 0.01. HIV-1 infection was assessed by measuring HIV-1 p24 antigen in cell-free culture supernatants obtained 7 days post-infection using an HIV-1 p24 antigen capture assay kit (SAIC, Frederick, MD).

Primer Extension Assays

Characterization of EFdA-TP as a Chain Terminator—DNA or RNA template was annealed to a 5'-Cy3-labeled DNA primer (3:1 molar ratio). To monitor the primer extension, the DNA/DNA or RNA/DNA hybrid (20 nM) was incubated at 37 °C with HIV-1 RT (20 nM) in a buffer containing 50 mM Tris (pH 7.8) and 50 mM NaCl (RT buffer). Subsequently, varying amounts of EFdA-TP or ddATP were added, and the reactions were initiated by the addition of 6 mM MgCl₂ to a final volume of 20 μ l. All dNTPs were present at a final concentration of 1 μ M. The reactions were terminated after 15 min by adding an equal volume of 100% formamide containing traces of bromophenol blue. The products were resolved on a 15% polyacrylamide 7 M urea gel. In this and subsequent assays, the gels were scanned with a phosphorimaging device (FLA 5000, FujiFilm). The bands for fully extended product were quantified using Multi Gauge software (FujiFilm), and the results were plotted as percent full extension using GraphPad Prism 4 to determine the IC₅₀ for EFdA-TP and other nucleotide analogs.

Steady State Kinetics—Steady state kinetic parameters, K_m and k_{cat} , for incorporation of EFdA-MP or dAMP were determined using single nucleotide incorporation in gel-based assays under saturating substrate conditions. The reactions were car-

ried out in RT buffer with 6 mM MgCl₂, 100 nM T_{d31}/P_{d18} or T_{r31}/P_{d18}, and 2.5 nM RT in a final volume of 20 μl and stopped at the indicated reaction times. The products were resolved and quantified as described above. *K_m* and *k_{cat}* were determined graphically using the Michaelis-Menten equation.

Incorporation of dNTP to the Template/Primer (T/P) Possessing Either EFdA-MP (T/P_{EFdA-MP}) or ddAMP (T/P_{ddAMP}) at the 3'-Primer Terminus—T/P_{EFdA-MP} and T/P_{ddAMP} were prepared by incubating 500 nM T_{d31}/P_{d18} with 1 μM HIV-1 RT in RT buffer and 6 mM MgCl₂. EFdA-TP (1 μM) or ddATP (5 μM) was added into the reaction and the mixture was incubated at 37 °C for 1 h. After incorporation of the nucleotide analogs, the T/P_{analog} was purified using the QIAquick nucleotide removal kit (Qiagen, Valencia, CA). Under these conditions, the extension of T/P to T/P_{EFdA-MP} or T/P_{ddAMP} was complete. Purified T/P_{EFdA-MP} (5 nM) was incubated with 20 nM HIV-1 RT in RT buffer and 6 mM MgCl₂. The first incoming nucleotide was added at different concentrations (0–100 μM) in the presence of the other dNTPs (1 μM). The reactions were incubated at 37 °C for 15 or 60 min.

Gel Mobility Shift Assays

Formation of RT·DNA Binary Complex—T/P_{EFdA-MP} and T/P_{ddAMP} were prepared using T_{d43}/P_{d18} as described above. Purified T/P_{EFdA-MP} or T/P_{ddAMP} (20 nM) was incubated at room temperature for 10 min with different concentrations of HIV-1 RT in RT buffer and 6 mM MgCl₂. RT was used at different concentrations to obtain RT/DNA ratios that ranged from 0.25 to 7.5. Four μl of 20% sucrose was added to each mixture in a final volume of 20 μl. The complexes were subsequently resolved on a native 6% polyacrylamide Tris borate gel and visualized as described above.

Formation of RT·DNA_{EFdA-MP}·dTTP Ternary Complex—Purified T/P_{EFdA-MP} or T/P_{ddAMP} (9 nM) was incubated at room temperature for 10 min with 100 nM HIV-1 RT, varying amounts of the next nucleotide (1–5000 μM) in RT buffer, and 6 mM MgCl₂. Prior to the addition of sucrose, 150 ng/μl heparin was added, and finally the products were resolved on native 6% polyacrylamide Tris borate gels and visualized as described above.

Site-specific Fe²⁺ Footprinting Assay

Site-specific Fe²⁺ footprints were monitored on 5'-Cy3-labeled DNA templates. T_{d43}/P_{d20} (100 nM) was incubated with HIV-1 RT (600 nM) in a buffer containing 120 mM sodium cacodylate (pH 7), 20 mM NaCl, 6 mM MgCl₂, and EFdA-TP (1 μM) to allow quantitative chain termination. Prior to treatment with Fe²⁺, complexes were preincubated for 7 min with increasing concentrations of the next nucleotide as indicated in Fig. 5A. The complexes were treated with ammonium iron sulfate (1 mM) as described previously (19). This reaction relies on autoxidation of Fe²⁺ (20) to create a local concentration of the hydroxyl radical, which cleaves the DNA at the nucleotide closest to the Fe²⁺ specifically bound to the RNase H active site.

PP_i- and ATP-dependent Excision and Rescue of T/P_{EFdA-MP} and T/P_{ddAMP}

PP_i-dependent Excision of T/P_{EFdA-MP} and T/P_{ddAMP}—Purified T/P_{EFdA-MP} and T/P_{ddAMP} (20 nM) were incubated at 37 °C with HIV-1 RT (60 nM) in the presence of 150 μM PP_i in RT buffer and 6 mM MgCl₂. Aliquots of the reaction were stopped at different times (0–30 min) and analyzed as described above.

PP_i-dependent Rescue of T/P_{EFdA-MP} and T/P_{ddAMP}—Purified T/P_{EFdA-MP} and T/P_{ddAMP} (20 nM) were incubated with HIV-1 RT (60 nM) at various concentrations of PP_i (0–150 μM) in RT buffer and 6 mM MgCl₂. The assay was performed in the presence of a large excess of competing dATP (100 μM), which prevented reincorporation of EFdA-MP, 0.5 μM dTTP, and 10 μM ddGTP. After an incubation of 10 min at 37 °C, the reactions were stopped and analyzed as described above.

ATP-dependent Rescue of T/P_{EFdA-MP} and T/P_{ddAMP}—Purified T/P_{EFdA-MP} and T/P_{ddAMP} (20 nM) were incubated with HIV-1 RT (60 nM) in the presence of 3.5 mM ATP, 100 μM dATP, 0.5 μM dTTP, and 10 μM ddGTP in RT buffer and 10 mM MgCl₂. Aliquots of the reaction were stopped at different time points (0–90 min) and analyzed as described above.

Molecular Modeling

Molecular models of two reaction intermediates that involve EFdA were built as follows. 1) A model of the ternary complex of HIV-1 RT·DNA·EFdA-TP (Fig. 7A) was built starting with the coordinates of the crystal structure of the HIV-1 RT·DNA·TFV-DP complex. The triphosphate of EFdA-TP was built using as a guide the corresponding atoms of TFV-DP in structure with PDB code 1T05 and of dTTP in PDB code 1RTD. The coordinates of the 4'-ethynyl sugar ring were from our NMR structure of EFdA⁵ showing that EFdA is in a North conformation similar to the sugar puckering observed in the crystal structure of 4'-ethynyl-2'-deoxycytidine (21). The structure of the EFdA-TP was assembled from its components using the sketch module of Sybyl 7.0 (Tripos Associates, St. Louis, MO), and minimized by the semiempirical quantum chemical method PM3 (22). The PM3 charges and the docking module of Sybyl 7.0 were used to dock the EFdA-TP at the RT dNTP-binding site (after removing the TFV-DP from 1T05) to generate the ternary complex HIV-1 RT·T/P·EFdA-TP. The final complex structure was minimized for 100 cycles using the AMBER force field with Coleman united charges on the protein and DNA molecules. 2) The model of the RT·T/P_{EFdA-MP} binary complex with primer 3'-terminal EFdA-MP at the pre-translocation nucleotide-binding site (N-site) (or dNTP-binding site) (Fig. 7B) was built using as a starting model our crystal structure of the pre-translocation complex RT·T/P_{AZT-MP} (PDB code 1N6Q). The structures of AZTMP and the base-pairing dA were replaced by EFdA-MP (built as in EFdA-TP above) and a dT, respectively, using the sketch module of Sybyl 7.0, and energy-minimized using the AMBER force field with Coleman united charges on the protein and DNA molecules.

Mechanism of HIV RT Inhibition by EFdA-TP

RESULTS

EFdA-TP Is a Highly Potent Inhibitor of HIV-1 RT—EFdA inhibits HIV-1 replication in phytohemagglutinin-activated PBMCs with an EC_{50} of 50 μ M (Table 2), consistent with previously published data obtained using T-cell lines (12, 13), and data published after completion of this work (23). The antiviral potency of EFdA is at least 4 orders of magnitude greater than the clinically used adenine nucleotide analog tenofovir and over 400-fold greater than that of AZT when assessed under the same conditions (Table 2). EFdA thus appears to be the most potent nucleoside inhibitor described to date of HIV-1 replication in primary cells. It is also interesting to note that EFdA is substantially more potent than analogs lacking a 3'-OH function (EFddA and EFd4A; Table 2). No cytotoxicity was noted at 10 μ M EFdA (data not shown), the highest concentration tested,

suggesting an *in vitro* selectivity index of over 200,000. To better understand the molecular basis for the exceptional antiviral potency of EFdA, we carried out a series of detailed *in vitro* evaluations of the impact of the active antiviral form of EFdA, namely EFdA-TP, on DNA synthesis catalyzed by purified HIV-1 RT.

We first compared the effect of EFdA-TP with other NRTI-TPs (ddATP, TFV-DP, AZTTP, and ddCTP) on RT-catalyzed DNA synthesis in *in vitro* primer extension assays using a nucleic acid T/P comprising a 100-nucleotide DNA template annealed to a Cy3-5'-labeled 18-nucleotide DNA primer (Table 1). As shown in Fig. 1B, EFdA-TP suppressed full-length DNA synthesis by RT in a dose-dependent manner. EFdA-TP was between ~1 and 2 orders of magnitude more effective at inhibiting RT-catalyzed DNA synthesis than any of the NRTIs evaluated. The IC_{50} for suppression of full primer extension by EFdA-TP was 14 nM using the longer T_{d100}/P_{d18} (Fig. 1, C and D). To confirm the high efficiency at which RT uses EFdA, we performed single nucleotide incorporation assays under steady state conditions (using T_{d31}/P_{d18} or T_{r31}/P_{d18} as a T/P, Table 1). Our results show that under these conditions the incorporation efficiency (k_{cat}/K_m) of EFdA-TP by RT is twice that for the natural dATP substrate and four times that for ddATP, primarily because of changes in the K_m of RT to these substrates (Table 3). Moreover, we found that the increase in incorporation efficiency of EFdA-TP could be even higher at different nucleic acid sub-

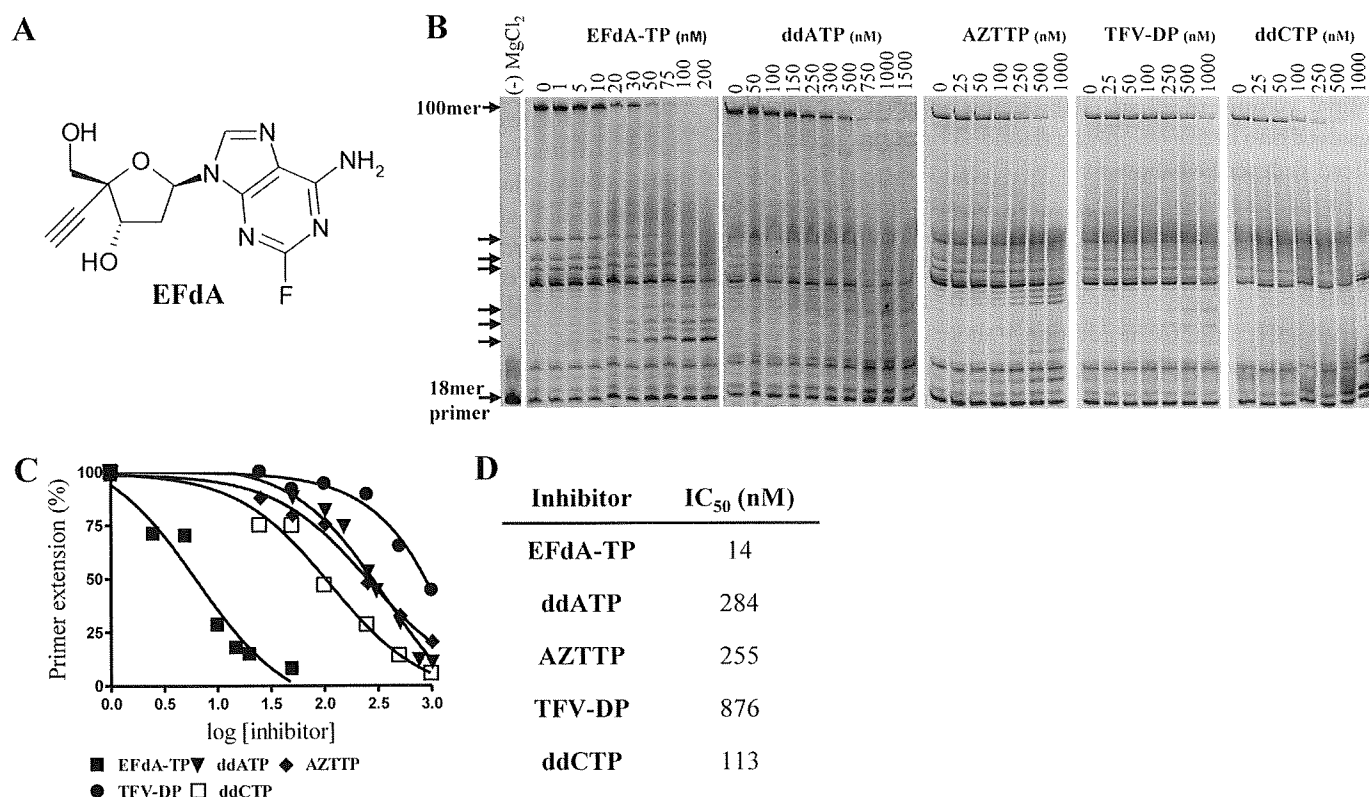

FIGURE 1. HIV RT inhibition by EFdA-TP and other NRTIs. A, structure of EFdA. B, primer extension by HIV-1 RT was observed in the presence of fixed concentrations of 4 dNTPs, T_{d100}/P_{d18} , and $MgCl_2$ and increasing concentrations of EFdA-TP, ddATP, AZTTP, TFV-DP, or ddCTP. The reactions were carried out for 15 min. The arrows denote stops of the elongating DNA chain where adenosine analogs (EFdA-TP, ddATP, or TFV-DP) were expected to be incorporated. The first lane is a negative control, where no $MgCl_2$ was added; it shows the length of the 18-mer primer. C, the 100-mer products synthesized by HIV-1 RT were quantified and plotted against increasing concentrations of various inhibitors. The data points were fitted by GraphPad Prism 4 using one-site competition nonlinear regression.

TABLE 3

Steady state kinetic parameters (K_m and k_{cat}) for EFdA-MP and dAMP incorporation by HIV-1 RTValues are means \pm S.D. of triplicate determinations and were determined from Michaelis-Menten equation using GraphPad Prism 4. ND, not determined.

dNTP	T/P (DNA/DNA)				T/P (RNA/DNA)			
	K_m	k_{cat}	k_{cat}/K_m	Selectivity ^a	K_m	k_{cat}	k_{cat}/K_m	Selectivity ^a
	nM	min ⁻¹	min ⁻¹ ·nM ⁻¹		nM	min ⁻¹	min ⁻¹ ·nM ⁻¹	
dATP	73.11 \pm 11	19.9 \pm 0.7	0.272	1	21.3 \pm 8	3.1 \pm 0.2	0.145	1
EFdA-TP	39.2 \pm 3	21.1 \pm 0.4	0.538	2	24.1 \pm 5	2.3 \pm 0.1	0.095	0.7
ddATP	97.0 \pm 9	15.4 \pm 0.3	0.159	0.6	ND	ND	ND	ND

^a Selectivity is the ratio of the incorporation efficiency (k_{cat}/K_m) of EFdA-MP or ddAMP over that of dAMP ($(k_{cat}/K_m)_{EFdA-MP}/(k_{cat}/K_m)_{dAMP}$ or $(k_{cat}/K_m)_{ddAMP}/(k_{cat}/K_m)_{dAMP}$).

FIGURE 2. Inhibition of DNA- and RNA-dependent DNA synthesis by EFdA-TP. *A*, T_{d31}/P_{d18} was incubated with HIV-1 RT for 15 min in the presence of 1 μ M dNTPs and $MgCl_2$ and increasing concentrations of EFdA-TP (0–1000 nM). The first lane (ddATP) shows the inhibition of primer extension by ddATP to identify points of adenosine analog (ddATP or EFdA-TP) incorporation (arrows: +1, +6, and +10). *B*, the primer extension under the same conditions with an RNA/DNA substrate containing an RNA template annealed to a DNA primer (T_{r31}/P_{d18}).

FIGURE 3. Incorporation of dNTP on EFdA-terminated template/primer ($T/P_{EFdA-MP}$). EFdA-TP was first incorporated at T_{d31}/P_{d18} by HIV-1 RT and purified as described under "Experimental Procedures." The incorporation of the next incoming nucleotide on $T/P_{EFdA-MP}$ was examined in the presence of HIV-1 RT and $MgCl_2$ and increasing concentrations of dTTP. All other dNTPs were at a concentration of 1 μ M. The reactions were stopped after 15 min (*A*) and 60 min (*B*).

strate sequences, more than 10 times higher than dATP (data not shown).

The EFdA-TP-mediated reduction in full-length DNA synthesis was accompanied by the concomitant appearance of products corresponding to the primer extension only at the length expected for the incorporation of adenosine nucleotides (indicated by arrows in Fig. 1*B*). Neither ddATP nor TFV-DP provided significant accumulation of this small DNA product.

EFdA-TP Inhibits DNA Synthesis Mainly at the Point of Incorporation—The stopping patterns of DNA synthesis were different in the presence of EFdA-TP compared with other dATP analogs such as ddATP and TFV-DP (marked by arrows in Fig. 1*B*). Hence, we used a shorter template (T_{d31}/P_{d18} (Table 1)), which allowed unambiguous identification of the stopping sites. As expected, the inhibitory potential of EFdA (and other NRTIs) appears lower in these shorter T/P (IC_{50} for suppression of full primer extension was 104 nM) in which there are fewer opportunities for incorporation (24). This substrate allows incorporation of dA, ddA, or EFdA at positions 1, 6, and 10 (Fig. 2). The results show that EFdA-TP causes major pauses at all possible points of incorporation (Fig. 2*A*, positions 1, 6, and 10), suggesting that EFdA-TP inhibits RT mainly as an obligate chain terminator. Notably, there was a distinct difference at position +6 of T_{d31}/P_{d18} , where we observed a strong stop not only at the point of incorporation but also at the position following (Fig. 2*A*, positions 6 and 7, respectively). These results suggest that in some cases EFdA-MP may also allow incorporation of an additional nucleotide depending upon the template sequence.

EFdA-TP inhibits both RNA- and DNA-dependent RT-catalyzed full-length DNA polymerization to comparable extents (Fig. 2). The selectivity for incorporation of EFdA-MP over dAMP ($(k_{cat}/K_m)_{EFdA-MP}/(k_{cat}/K_m)_{dAMP}$) was slightly increased when we used DNA/DNA versus RNA/DNA template/primers (Table 3, 2 versus 0.7). Notably, the overall pausing pattern due to inhibition by EFdA-TP differs depending on whether the template is RNA or DNA. Inhibition differences based on type and sequence of template are currently under investigation.

Extension of EFdA-terminated T/P ($T/P_{EFdA-MP}$)—The data in Figs. 1 and 2 suggest that EFdA-TP can act as a terminator of RT-catalyzed DNA synthesis in a manner similar to that of other NRTI-TPs. We therefore examined the efficiency of nucleotide additions to primers that were synthesized to already possess a 3'-terminal EFdA-MP. Fig. 3 shows that the primer extension from EFdA-MP is very limited and is evident only at very high and nonphysiological concentrations (>50 μ M) of the next nucleotide and with extended reaction times (Fig. 3*B*, 60-min incubation). It therefore appears that EFdA acts as a *de facto* chain terminator, despite the presence of a 3'-OH function.

RT Binds T/P_{ddAMP} and $T/P_{EFdA-MP}$ at Similar Efficiencies—A possible reason for the inability of RT to efficiently extend the EFdA-MP-terminated primer is that it binds $T/P_{EFdA-MP}$ with less affinity than it does a T/P lacking a 3'-terminal EFdA-MP nucleotide. We therefore used gel mobility shift assays to compare the stabilities of the binary complexes of RT with T/P possessing either EFdA-MP ($T/P_{EFdA-MP}$) or ddAMP

Mechanism of HIV RT Inhibition by EFdA-TP

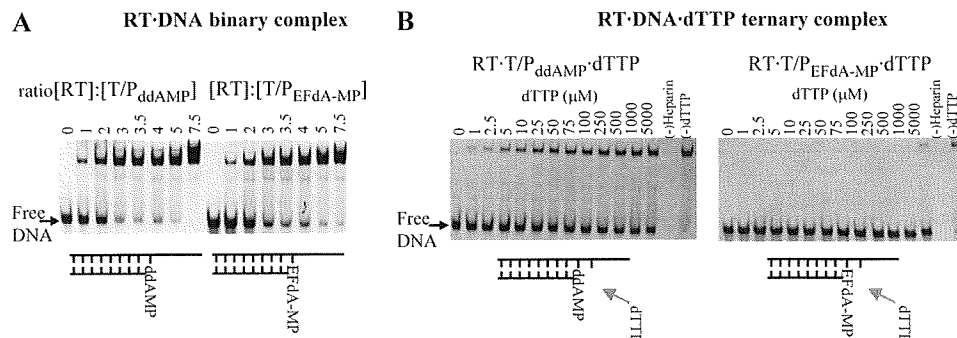

FIGURE 4. Effect of ddA or EFdA on formation of binary and ternary complexes. *A*, formation of a binary complex between RT and T/P_{dddAMP} or T/P_{EFdA-MP}. Purified T/P_{dddAMP} or T/P_{EFdA-MP} (20 nM) was incubated with HIV-1 RT at the indicated molar ratios and resolved by nondenaturing gel electrophoresis. *B*, formation of a ternary complex between RT and T/P_{dddAMP} or T/P_{EFdA-MP} and incoming dTTP. The stability of the ternary complexes was analyzed by incubating 100 nM RT and 9 nM T/P_{dddAMP} or T/P_{EFdA-MP} in the presence of increasing dTTP concentrations and heparin, which acted as an enzyme trap. In the absence of dTTP, the T/P-RT binary complex is unstable (lane 0), as RT dissociates from the T/P and is trapped by heparin.

(T/P_{dddAMP}) at the 3'-primer terminus (T/P chain terminated by EFdA-MP or ddAMP). As shown in Fig. 4*A*, RT binds T/P_{EFdA-MP} with an apparent affinity comparable with that of the normal T/P (K_d for RT·T/P_{EFdA-MP} = 51 nM; K_d for RT·T/P_{dddAMP} = 42 nM). This observation suggests that RT is inhibited at a downstream step in the polymerization reaction.

RT Is Unable to Form a Stable Ternary Complex with T/P_{EFdA-MP} and dNTP—The next step in the DNA polymerization mechanism is the binding of the next complementary dNTP to RT·DNA, thus forming the ternary complex that precedes catalysis. To determine whether EFdA exerts its inhibitory effect by interfering with the formation of a stable ternary complex with the incoming dNTP, we used a gel-based nondenaturing electrophoresis assay (25) that detects the ternary complex formed by RT·T/P and the next complementary dNTP (in this case, dTTP). In this assay, the stability of the ternary complex is assessed by the persistence of the RT·DNA·dNTP complex upon addition of a competing heparin trap (25). As seen in Fig. 4*B* (left panel), the ternary complex formed by RT with T/P_{dddAMP} and dTTP is quite stable. In contrast, no significant amount of ternary complex was noted in assays using T/P_{EFdA-MP} even at very high dTTP concentrations (Fig. 4*B*, right panel).

Incorporation of EFdA-TP into DNA (T/P_{EFdA-MP}) Decreases Translocation of RT—The inability of RT to form a stable ternary complex with T/P_{EFdA-MP} and the next complementary dNTP could arise from several factors including (i) the inability of the 3'-terminal EFdA-MP primer to efficiently translocate from the N-site (which is also the pre-translocation site) to the post-translocation primer site (P-site), thereby preventing the next incoming nucleotide from binding; and (ii) the fact that T/P_{EFdA-MP} can translocate, but the presence of unnatural substituents in the primer 3'-terminal EFdA-MP (4'-ethynyl and 2-fluoro) may alter geometric and electronic parameters at the primer end, thus preventing efficient incorporation of the next incoming dNTP such that catalysis cannot occur. These two different possibilities place the nucleic acid at different positions/registers with respect to a site-specific landmark in RT, the metal-binding ribonuclease H (RNase H) active site, as shown in the schematic of Fig. 5*B*. We therefore used a site-

specific Fe²⁺ footprinting assay (19) to determine whether the primer 3'-terminal EFdA-MP of the RT·T/P_{EFdA-MP} complex resides primarily in the pre- (N-site) or post-translocation (P-site) state in the absence and the presence of varying levels of the incoming complementary dNTP, which serves to "force" the 3'-primer terminus from the pre-translocation (N-site) to the post-translocation site (P-site). As shown on Fig. 5*A* (left panel), in the absence of dTTP (first lane), primers with a 3'-terminal ddAMP are located in both the pre- and post-translocation sites in approximately equal amounts, and the addition of

the next complementary nucleotide (dTTP) forces the primer 3'-end almost entirely into the post-translocation site. In contrast, in the absence of dTTP, primers with a 3'-terminal EFdA-MP are located exclusively in the pre-translocation site (Fig. 5*A*, right panel, first lane). The next complementary nucleotide (dTTP) is unable to shift the position of the 3'-EFdA-MP except at very high (nonphysiological) concentrations.

Because it is physically impossible for the incoming dNTP to bind at the N-site (dNTP-binding site) when it is occupied by the 3'-primer terminus of the non-translocated T/P_{EFdA-MP}, the present data demonstrate that the apparent termination of RT-catalyzed DNA synthesis upon incorporation of EFdA-MP arises from the inability of the 3'-EFdA-MP-terminated primer/template (T/P_{EFdA-MP}) to efficiently translocate to the P-site and allow incorporation of the next dNTP. Moreover, the latter is unable to force translocation of the 3'-EFdA-MP-terminated primer strand. The inability of the 3'-EFdA-MP-terminated primer to translocate to allow binding of the next complementary dNTP effectively prevents continued elongation of the nascent viral DNA, despite the presence of the 3'-OH on EFdA. Therefore, we propose that EFdA acts as a *translocation-defective reverse transcriptase inhibitor*.

Phosphorolytic Excision of EFdA-MP—Two major mechanisms account for HIV resistance to NRTIs (26). One is based on NRTI discrimination, where the mutant RT preferentially incorporates the natural dNTP rather than the NRTI-TP. The other major resistance mechanism involves ATP-mediated phosphorolytic excision of the incorporated chain-terminating NRTI from the 3'-end of the primer (27, 28). We and others have previously shown that for excision to occur, the 3'-end of the primer must be positioned at the pre-translocation or N-site of RT (19, 29, 30). As we have already shown, the 3'-EFdA-MP-terminated primer strand binds predominantly in a pre-translocation mode. This suggests that EFdA-terminated primers might be especially susceptible to RT-catalyzed phosphorolytic removal of the terminating EFdA-MP. To assess this possibility we carried out primer unblocking experiments using nucleic acid substrates having at the 3'-primer terminus either EFdA-MP or ddAMP (T/P_{EFdA-MP} or T/P_{dddAMP}, respectively). The quantitation of results in Fig. 6*A*

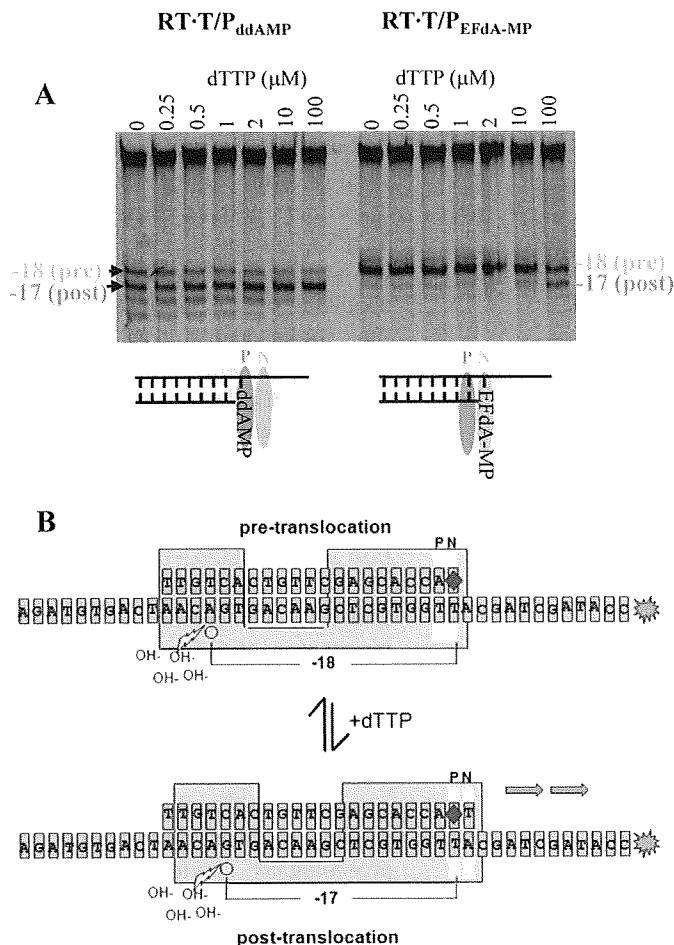

FIGURE 5. Determination of the translocation state of RT bound to T/P_{ddAMP} and $T/P_{EFdA-MP}$ template/primers. *A*, the translocation state of RT after EFdA-MP incorporation was determined using site-specific Fe^{2+} footprinting. T/P_{ddAMP} or $T/P_{EFdA-MP}$ (100 nM) with 5'-Cy3 label on the DNA template (see Fig. 5B) was incubated with HIV-1 RT (600 nM) and various concentrations of the next incoming nucleotide (dTTP) (as indicated). The complexes were treated for 5 min with ammonium iron sulfate (1 mM) and resolved on a polyacrylamide 7 M urea gel. An excision at position -18 indicates a pre-translocation complex, whereas the excision at position -17 represents a post-translocation complex. The scheme below the gel images indicates that in the absence of incoming dNTP, T/P_{ddAMP} is bound mostly in a post-translocation state, whereas $T/P_{EFdA-MP}$ is bound in a pre-translocation state, with EFdA-MP positioned at the N-site. *B*, schematic of the excision assay. Depending on whether the 3'-primer terminus is positioned at the pre-translocation (N-site) or post-translocation (P-site) site, cleavage is observed on the 5'-labeled template strand at positions -18 or -17, respectively. The addition of varying levels of the incoming complementary dNTP serves to force the 3'-primer terminus from the N-site to the P-site.

shows that the rate of hydrolysis of ddAMP- and EFdA-MP-terminated primers was 0.5 and 1.6 min^{-1} , respectively. We also considered whether the EFdA-TP formed upon pyrophosphorytic removal of the 3'-terminal EFdA-MP was promptly reincorporated. We tested this possibility using so-called phosphorolysis "rescue" assays, where in addition to the PP_i that would react with the EFdA-MP from the 3'-primer terminus to produce EFdA-TP, we also included a high concentration of dATP that would compete with and prevent reincorporation of EFdA-TP. In the case of high excision activity, we expected to see higher bands corresponding to rescued and extended primers. Indeed, substantially more primer extension was noted in PP_i - or ATP-mediated rescue assays using 3'-terminal

EFdA-MP primers (Fig. 6, *C* and *D*, right panels) than in assays using primers with 3'-terminal ddAMP (Fig. 6, *C* and *D*, left panels). The rate for the ATP-dependent rescue of EFdA-MP-terminated primer was 0.063 min^{-1} . The corresponding rate for the ATP-dependent rescue of the ddAMP-terminated primer could not be calculated because the reaction was very slow. Collectively, these data suggest that 3'-terminal EFdA-MP is phosphorolytically excised more efficiently than ddAMP, consistent with its preferential positioning at the phosphorolysis-susceptible pre-translocation N-site.

Molecular Basis of RT Inhibition by TDRTIs—To understand the molecular basis of RT inhibition by EFdA-TP, we built molecular models of complexes that represent the following intermediates of the DNA polymerization reaction: 1) a pre-catalytic RT·DNA·EFdA-TP ternary complex and 2) a complex that corresponds to the product of EFdA-MP incorporation prior to translocation. Previously we had solved crystal structures representing both types of these intermediates for other NRTIs (29, 31), and the model building was guided by the structural characteristics of these complexes. Moreover, we built the EFdA sugar ring in both models in a 3'-endo (North) conformation based on our unpublished NMR experimental data, which clearly show that the equilibrium of the geometries of the EFdA sugar ring overwhelmingly favors the 3'-endo conformation (North). The RT·DNA·EFdA-TP ternary complex model was built using as a starting structure the coordinates of our RT·DNA·TFV-DP crystal structure (PDB code 1T05), not only because it is the highest resolution structure of an RT ternary complex but also because it is the only structure of RT in complex with an analog of deoxyadenosine triphosphate (31). The model of the RT·DNA·EFdA-TP complex represents the step of EFdA-TP binding to the preformed RT·DNA complex (Fig. 7A). It had no significant differences from the crystal structures of the ternary complexes of RT with DNA and TFV-DP (PDB code 1T05) or dTTP (PDB code 1RTD). It shows that the 4'-ethynyl of EFdA-TP is favorably positioned in a hydrophobic pocket formed by Ala-114, Tyr-115, Phe-160, and Met-184 and the aliphatic portion of Asp-185. These interactions are similar to those that have been proposed for binding of 4'-Ed4T, a related NRTI thymidine analog that also has a 4'-substitution but no 3'-OH group (32). These interactions are also consistent with the observed high efficiency of EFdA-MP incorporation by RT (Fig. 1D). Similar interactions stabilize the RT·DNA_{EFdA-MP} pre-translocation binary complex, which has the primer 3'-terminal EFdA-MP positioned at the N-site (Fig. 7B, pre-translocation complex). These favorable interactions are also consistent with the enhanced binding of $T/P_{EFdA-MP}$ in a pre-translocated mode (Fig. 5).

DISCUSSION

The single most distinguishing feature of NRTIs used in HIV therapy is the absence of a 3'-OH. This property results in termination of further viral DNA synthesis upon incorporation of the inhibitor into the nascent viral DNA. We have shown (10, 13) that certain nucleoside analogs that retain the 3'-OH group can exert potent antiviral activity. One of these, EFdA, inhibits HIV-1 replication in PBMCs with a potency that is several orders of magnitude greater than that of any of the current

Mechanism of HIV RT Inhibition by EFdA-TP

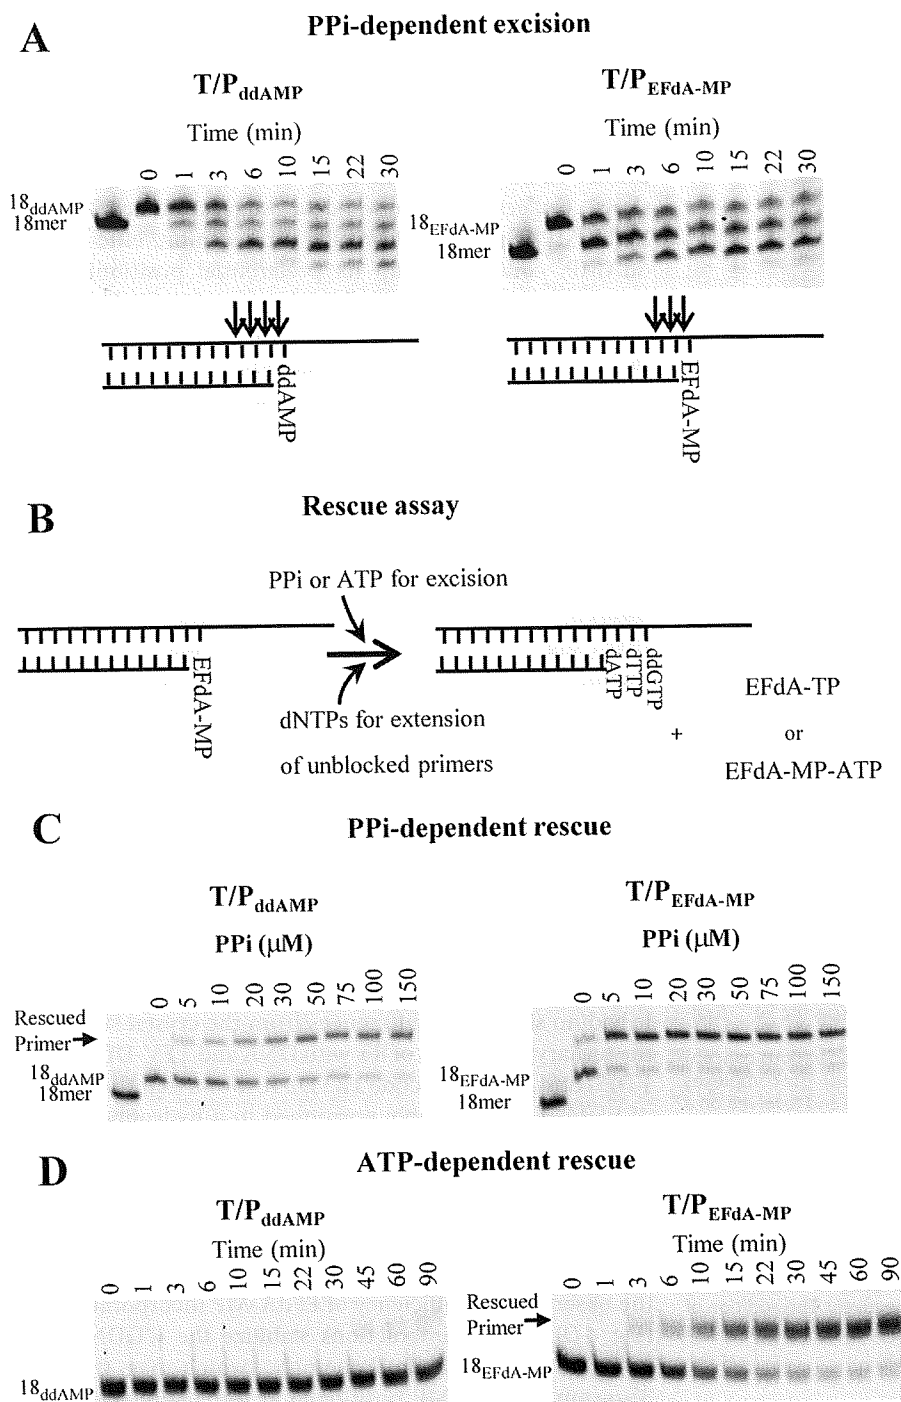

FIGURE 6. PP_i and ATP-dependent unblocking of ddAMP and EFdA-MP terminated primers. A, PP_i-dependent unblocking of T/P_{ddAMP} and T/P_{EFdA-MP}. Purified T/P_{ddAMP} or T/P_{EFdA-MP} was incubated with HIV-1 RT in the presence of 6 mM MgCl₂ and 150 μM PP_i at 37 °C. Aliquots were removed and reactions stopped at the indicated time points (0–30 min). Cleavage sites are indicated with arrows in the schemes below the gels. B, schematic representation of PP_i- and ATP-dependent rescue assay. The excision products of PP_i- and ATP-dependent excision of EFdA-MP are EFdA-TP and the EFdA-MP-ATP dinucleoside tetraphosphate, respectively. C, PP_i-dependent rescue of T/P_{ddAMP} and T/P_{EFdA-MP}. Purified T/P_{EFdA-MP} or T/P_{ddAMP} was incubated with HIV-1 RT in the presence of various amounts of PP_i (0–150 μM), dATP (100 μM), dTTP (0.5 μM), or ddGTP (10 μM) and 10 mM MgCl₂ at 37 °C. Aliquots of the reaction were stopped after 10 min. D, ATP-dependent rescue of T/P_{ddAMP} or T/P_{EFdA-MP}. Purified T/P_{EFdA-MP} or T/P_{ddAMP} was incubated with HIV-1 RT in the presence of ATP (3.5 mM), dATP (100 μM), dTTP (0.5 μM), or ddGTP (10 μM) and 10 mM MgCl₂ at 37 °C. Aliquots of the reaction were stopped at the indicated time points (0–90 min).

clinically used NRTIs (Table 2 and Ref. 23), consistent with the inhibitory data obtained in transformed T-cell lines (13). The molecular basis for this exceptional antiviral activity of EFdA

has to date been unclear. The detailed *in vitro* biochemical studies presented in this article show that EFdA inhibits HIV-1 reverse transcriptase mainly by blocking translocation after incorporation at the 3'-primer end and functioning as a TDRTI. The specificity of inhibition can vary depending on the type and sequence of the template (Fig. 2). Our studies also suggest that both the 3'-OH and the 4'-ethynyl groups of EFdA play important roles in the high antiviral potency exerted by this nucleoside analog.

The 4'-ethynyl group is essential for the mechanism of EFdA inhibition of RT-catalyzed DNA synthesis. The present work shows that EFdA-TP acts mainly as a potent terminator of RT-catalyzed DNA synthesis, despite having a 3'-OH group. It is possible that the presence of a 4'-ethynyl substitution on the ribose ring somehow affects the geometry and reactivity of its 3'-OH. However, in the presence of physiological concentrations of dNTPs (<50 μM) the chain terminating activity of EFdA appears to arise mainly from the difficulty of RT to translocate the 3'-EFdA-MP-terminated primer (T/P_{EFdA-MP}) following incorporation of the inhibitor. Under these circumstances the dNTP-binding site is not accessible, and incorporation of the next complementary nucleotide is prevented (Fig. 7C). Hence, EFdA appears to act as a translocation-defective RT inhibitor. The 4'-ethynyl moiety appears to be the critical factor in the difficulty presented by translocation of DNA primers with a 3'-terminal EFdA-MP residue. Our molecular model of the RT·DNA·EFdA-TP ternary complex suggests that the 4'-ethynyl moiety fits nicely into a hydrophobic pocket in the RT active site defined by residues Ala-114, Tyr-115, Phe-160, and Met-184 and the aliphatic portion of Asp-185 (Fig. 7A), similar to the proposed interactions of 4'-Ed4T at the same

site (32). Once EFdA-MP has been added to the primer end to form the pre-translocation (or N-site) reaction product, these same RT residues serve to stabilize the terminal EFdA-MP in

FIGURE 7. Molecular models representing intermediates of the DNA polymerization reaction. A, molecular model of a ternary complex among RT, DNA, and EFdA-TP. The primer is bound at the P-site, and the incoming EFdA-TP is bound at the N-site. The 4'-ethynyl group of EFdA-TP is bound at a hydrophobic pocket (shown by a yellow arrow) defined by residues Met-184, Ala-114, Tyr-115, and Phe-160 and the aliphatic chain of Asp-185. For

the pre-translocation state (Fig. 7B). Hence, the stabilization of the primer 3'-terminal EFdA-MP in the pre-translocation state helps it to remain in a position antagonistic to further nucleotide addition and to inhibit DNA polymerization (Fig. 7C).

We have observed that in one instance RT stopped not only at the point of EFdA incorporation but also at the position following (Fig. 2A, positions 6 and 7, respectively). Interestingly, we found that RT has enhanced translocation efficiency at this site, both on T/P_{EFdA-MP} and on T/P_{ddAMP} (data not shown). It appears that some translocated T/P_{EFdA-MP} is also elongated by an additional nucleotide. Further polymerization may be inhibited by unfavorable interactions between the 4'-ethynyl group in the elongated template/primer (T/P_{EFdA-MP-dNMP}) with protein residues upstream in the DNA-binding cleft. The effect of template on the inhibition mechanism by EFdA is the subject of an ongoing investigation.

RT-catalyzed phosphorolytic excision of chain-terminating NRTIs is a major mechanism of HIV-1 resistance to the nucleoside analog class of therapeutics (26–28, 33). Our previous studies have shown that the NRTI phosphorolytic excision reaction is favored when the primer 3'-terminal nucleotide is in the pre-translocation or N-site (19, 34). The preference of the primer 3'-terminal EFdA-MP to remain in this site suggests that terminal EFdA-MP should undergo facile phosphorolytic removal. EFdA-MP was subject to excision by pyrophosphorolysis somehow faster than ddAMP, which tends to localize in the post-translocation site when at the 3' terminus of the primer (see Fig. 5A). Although EFdA-MP can undergo excision, this process is not overly efficient, apparently because once the nucleotide is excised through pyrophosphorolysis to form EFdA-TP, the latter is rapidly reincorporated. These findings suggest that phosphorolysis may not play a significant role in HIV-1 resistance to EFdA, consistent with the relatively small loss of antiviral potency of EFdA against excision-enhanced HIV-1-containing mutations associated with resistance to AZT (13).

The importance of the 3'-OH in antiviral activity of EFdA is perhaps best highlighted by the observation that EFdA is 10,000-fold more potent at inhibiting HIV-1 replication in PBMCs than is the identical nucleoside lacking a 3'-OH, namely EFddA (Table 2). The 3'-OH on EFdA appears to play a number of roles in contributing to the exceptional antiviral potency of the compound. The 3'-OH on natural dNTP substrates contributes to the efficiency with which RT uses these substrates, and in general NRTIs that lack a 3'-OH are used less efficiently by RT than the base-analogous dNTP (35) (Table 3). Our *in vitro* biochemical data demonstrate that EFdA-TP is approximately 1 and 2 orders of magnitude more potent an inhibitor of RT-catalyzed DNA synthesis *in vitro* than are the

purposes of clarity the p66 fingers subdomain is not shown. B, molecular model of RT bound to EFdA-MP-terminated T/P immediately after incorporation of the inhibitor at the primer terminus and before translocation. The EFdA-MP of the 3'-primer terminus is positioned at the N-site. C, schematic representation of RT inhibition by EFdA. After incorporation of EFdA-MP at the 3'-primer terminus RT remains bound to T/P_{EFdA} mostly in a pre-translocation binding mode (top). In that binding mode the EFdA-MP at the 3'-primer terminus blocks binding of the incoming dNTP, thus inhibiting DNA polymerization.

Mechanism of HIV RT Inhibition by EFdA-TP

adenine-based NRTIs ddATP and TFV-DP, respectively (Fig. 1D), neither of which has a 3'-OH. Indeed, it appears that under identical conditions, RT is at least twice as likely to use EFdA-TP as a substrate over the natural nucleotide dATP (Table 3). This suggests that during HIV-1 reverse transcription, EFdA-TP might be preferentially incorporated, thereby leading to early and profound chain termination and contributing to the observed potent antiviral activity of this nucleoside analog.

NRTIs are administered therapeutically as prodrugs; these must undergo phosphorylation in target cells in order to exert their antiviral activity. The lack of a 3'-OH on current clinically used NRTIs can reduce recognition by cellular nucleoside/nucleotide kinases that have evolved to interact with the 3'-OH present in their natural nucleoside substrates (9). Preliminary studies suggest that EFdA appears to undergo rapid and facile intracellular conversion to the active antiviral EFdA-TP (36), showing that the 4'-ethynyl group does not interfere with recognition by cellular nucleoside/nucleotide kinases. Furthermore, the presence of fluorine at position 2 of the adenine base of EFdA helps to stabilize intracellular levels of EFdA and its phosphorylated products by hindering adenosine deaminase-catalyzed degradation of the molecule (13). Thus, both the 2-fluoro and the 3'-OH of EFdA may contribute to the intracellular accumulation of the antiviral EFdA-TP, thereby leading to its pronounced antiviral activity. We are presently carrying out detailed studies of the intracellular pharmacokinetics of EFdA in comparison with other NRTIs to better understand the dynamics of EFdA phosphorylation and turnover as contributors to the exceptional potency and persistence of its antiviral activity.

Other nucleoside analog inhibitors of HIV-1 RT that possess a 3'-OH have been described (21, 37–42), although these have mechanisms of action quite distinct from that of EFdA. North-methanocarpa-2'-deoxyadenosine triphosphate and North-methanocarpa-2'-thymidine triphosphate inhibit HIV-1 RT *in vitro* by a mechanism of delayed chain termination, where RT-catalyzed DNA synthesis pauses after the addition of several nucleotides following incorporation of the inhibitor (38, 39). Neither of these compounds has antiviral activity, presumably because of poor intracellular phosphorylation. Entecavir is a nucleoside analog with a 3'-OH that is approved for treatment of hepatitis B infection. Entecavir-TP also has been shown to inhibit HIV-1 RT-catalyzed DNA synthesis by a mechanism of delayed chain termination (40). Entecavir has only weak antiviral activity against HIV-1.

Additionally, nucleoside analogs substituted at the 4'-position have also been described previously (43–46). For example, 4'-azidothymidine and 4'-azidoadenosine both inhibit HIV-1 replication (46) although with potencies 200–2000-fold less than that of EFdA. Both 4'-azido nucleosides also have poor *in vitro* selectivity indices because of significant cytotoxicity. Azidothymidine-TP was shown to inhibit RT-catalyzed DNA synthesis by a type of delayed chain termination; incorporation of two sequential azidothymidine-MP molecules blocked DNA synthesis (44, 45). 4'-Methyl thymidine and 4'-ethyl thymidine both seem to cause pauses and stops in DNA synthesis at the point of incorporation (39). However, neither of these com-

pounds has antiviral activity, because they cannot be phosphorylated by cellular nucleoside kinases. An analog of d4T that has a 4'-ethynyl substitution (Ed4T) is ~10 times more active than the parent compound (47, 48). Because Ed4T lacks a 3'-OH, it inhibits RT as a conventional chain terminator. Interestingly, Ed4T is a better substrate than d4T for phosphorylation by human thymidine kinase 1 (47–50), a property that leads to its increased antiviral potency compared with d4T. The antiviral activity of Ed4T is ~50-fold lower than that of EFdA.

In summary, EFdA is a TDRTI with two functionalities lacking in current therapeutic NRTIs, namely a 4'-ethynyl group and a 3'-OH. These additional properties impart superior antiviral activity to the compound and contribute to its mechanism of action, namely inhibition of primer translocation following EFdA-MP incorporation. This mechanism allows EFdA to act mainly as a *de facto* chain terminator of RT-catalyzed DNA synthesis, despite the presence of a 3'-OH. The present study validates RT nucleic acid translocation as a potential therapeutic target.
