

approach. However, the TDE may have detected wall motion of a considerably wide area near the LAA apex because the ultrasonic amplitude of TDE for the LAA wall velocity is much greater than that of blood flow signals. Thus, the values of TDE for LAA may show the maximum wall velocity near the LAA apex. Moreover, signals from adjacent structures such as the aorta and mitral valve ring may be present, but these signals can be excluded from the LAA contraction and relaxation signals by time analysis of monitoring ECG.

In this study, we analyzed only a single LAA region. However, each region in the LAA wall may show different myocardial velocities. Further studies are required to elucidate the significance of regional wall motion analysis of LAA.

Conclusions:

TDE by TTE may be a feasible noninvasive method for assessing LAA function. Relaxation of LAA may decrease significantly with aging and may be accompanied by age-related impairment of LV relaxation.

CORONARY HEART DISEASE (CHD) is a major cause of disability and premature death throughout the world.¹ Epidemiological studies have demonstrated an inverse association between physical fitness and the incidence of CHD or all-cause mortality in healthy or asymptomatic participants. Physical fitness is typically expressed as cardiorespiratory fitness (CRF) and is assessed by exercise tolerance testing²; however, it is rare for clinicians to consider CRF when evaluating future risk of CHD.³

A major reason for lack of consideration of CRF as a marker of CHD risk may be that the quantitative association of CRF for cardiovascular risk is not well established. The degree of risk reduc-

Context Epidemiological studies have indicated an inverse association between cardiorespiratory fitness (CRF) and coronary heart disease (CHD) or all-cause mortality in healthy participants.

Objective To define quantitative relationships between CRF and CHD events, cardiovascular disease (CVD) events, or all-cause mortality in healthy men and women.

Data Sources and Study Selection A systematic literature search was conducted for observational cohort studies using MEDLINE (1966 to December 31, 2008) and EMBASE (1980 to December 31, 2008). The Medical Subject Headings search terms used included *exercise tolerance, exercise test, exercise/physiology, physical fitness, oxygen consumption, cardiovascular diseases, myocardial ischemia, mortality, mortalities, death, fatality, fatal, incidence, or morbidity*. Studies reporting associations of baseline CRF with CHD events, CVD events, or all-cause mortality in healthy participants were included.

Data Extraction Two authors independently extracted relevant data. CRF was estimated as maximal aerobic capacity (MAC) expressed in metabolic equivalent (MET) units. Participants were categorized as low CRF (<7.9 METs), intermediate CRF (7.9-10.8 METs), or high CRF (≥ 10.9 METs). CHD and CVD were combined into 1 outcome (CHD/CVD). Risk ratios (RRs) for a 1-MET higher level of MAC and for participants with lower vs higher CRF were calculated with a random-effects model.

Data Synthesis Data were obtained from 33 eligible studies (all-cause mortality, 102 980 participants and 6910 cases; CHD/CVD, 84 323 participants and 4485 cases). Pooled RRs of all-cause mortality and CHD/CVD events per 1-MET higher level of MAC (corresponding to 1-km/h higher running/jogging speed) were 0.87 (95% confidence interval [CI], 0.84-0.90) and 0.85 (95% CI, 0.82-0.88), respectively. Compared with participants with high CRF, those with low CRF had an RR for all-cause mortality of 1.70 (95% CI, 1.51-1.92; $P < .001$) and for CHD/CVD events of 1.56 (95% CI, 1.39-1.75; $P < .001$), adjusting for heterogeneity of study design. Compared with participants with intermediate CRF, those with low CRF had an RR for all-cause mortality of 1.40 (95% CI, 1.32-1.48; $P < .001$) and for CHD/CVD events of 1.47 (95% CI, 1.35-1.61; $P < .001$), adjusting for heterogeneity of study design.

Conclusions Better CRF was associated with lower risk of all-cause mortality and CHD/CVD. Participants with a MAC of 7.9 METs or more had substantially lower rates of all-cause mortality and CHD/CVD events compared with those with a MAC of less than 7.9 METs.

tion associated with each incremental higher level of CRF, the criteria for low CRF, and the magnitude of risk associated with low CRF have been inconsistent among studies. Our goal of this meta-analysis was to systematically review the quantitative relationship between CRF and all-cause mortality and CHD or cardiovascular disease (CVD) events in healthy individuals.

METHODS

Search Strategy

The meta-analysis was conducted according to the checklist of the Meta-analysis of Observational Studies in Epidemiology.⁴ We performed a systematic literature search of MEDLINE (1966 to December 31, 2008) and EMBASE (1980 to December 31, 2008) for observational cohort studies. Three search themes were combined using the Boolean operator *and*. The first keywords were related to CRF (combined exploded versions of the Medical Subject Headings [MeSH] as follows: *exercise tolerance OR exercise test OR exercise/physiology OR physical fitness OR oxygen consumption*); the second keywords were related to the outcome of this meta-analysis (combined unexploded version of MeSH [*cardiovascular diseases*] or the exploded version of MeSH [*myocardial ischemia*]) or the following text words (*mortality OR mortalities OR death OR fatality OR fatal OR incidence* OR event* OR morbidity*); and the third keywords were related to risk estimates (combined text words as follows: *regression analysis OR regression model* OR statistical regression* OR logistic regression* OR logit regression* OR logistic model* OR logit model* OR Cox model OR hazard model OR odds ratio* OR ORs OR relative odds OR risk ratio* OR relative risk* OR RRs*). We also included studies published in non-English language. In addition, we searched the reference lists of all identified relevant publications.

Inclusion and Exclusion Criteria

We included papers if (1) CRF was assessed by an exercise stress test; (2) the association of CRF with all-cause mortal-

ity and with CHD or CVD was evaluated; (3) CRF could be assessed as maximal aerobic capacity (MAC), expressed in units of metabolic equivalents (METs), which is defined as the ratio of intensity of physical activity to that of sitting at rest; and (4) risk ratios (RRs) and their corresponding 95% confidence intervals (CIs) relating to each category of MAC were reported or could be calculated. We excluded studies that were intended only for patients having a specific disease that presented a major risk factor, such as diabetes, hypertension, and familial hypercholesterolemia, as well as studies that included patients with CHD or chronic heart failure.

To avoid double counting of a cohort, study selection was limited to a single set of results when multiple publications were available for a single observational study. The first priority for selection was the study with the longest follow-up and the second was the study with full cohort analysis covering the largest number of participants among articles from a single cohort. We conducted 2 separate meta-analyses for risk of all-cause mortality and CHD or CVD in relation to CRF. When an individual study provided data on both CHD or myocardial infarction (MI) and CVD,^{5,7} priority for data abstraction was given to CVD because CVD is more comprehensive than CHD and MI. Similarly, if data on both events and deaths were provided,^{6,8,9} priority was given to events.

We combined CHD and CVD into 1 outcome (CHD/CVD), which included studies whose outcome was a CVD event, CVD death, CHD event, or CHD death, because the number of eligible studies included was limited. Although criteria for the end point in CHD varied from study to study, the end points that we specified as CHD outcome in our meta-analysis were (1) death from MI; (2) death from CHD including MI; and (3) a CHD event, a term which meant either death from CHD, sudden cardiac death, occurrence of nonfatal CHD, or nonfatal MI. Additionally, we included studies whose outcome was either CVD death (ie, encompassing death from cardiovascular causes other than CHD) or CVD

events (ie, lumping together fatal and nonfatal CVD).

Data Abstraction

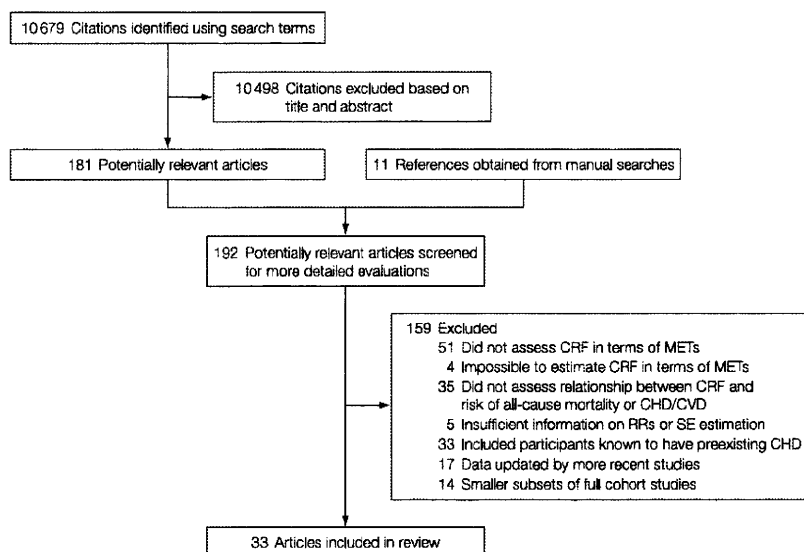

Data abstracted were the first author's name, year of publication, country of origin, specific outcomes, duration of follow-up, methods for outcome assessment, instrument or methods for measurement of CRF, whether maximal exercise testing (defined as instructing participants to continue exercise until their maximal workload) was conducted, mean of participants' age, proportion of men, number of participants and number of new cases (ie, deaths or events) during the observational periods, adjusted variables, and whether participants with abnormal electrocardiogram findings (ie, ST elevation/depression) during exercise testing were included. Two of our investigators (S. Kodama and H. Sone) independently reviewed each published paper and extracted relevant information. Any disagreement was resolved by consensus.

In studies using CRF as a categorical variable, we standardized all reported RRs into comparison of the risk of the lower CRF group with that in the higher CRF group. Therefore, when the lowest CRF group was referent, we converted the reported RR into its reciprocal. When a study provided several RRs, such as unadjusted and adjusted RRs, the most completely adjusted RR was used. The standard error (SE) of each RR was derived from 95% CIs or *P* values. If data related to RR and its corresponding SE were not provided, their value was directly calculated using data on the number of participants (*P*) and new cases (*C*) of risk and the reference (ref) groups in each comparison, using the equation:

$$RR = [(C_{risk}/P_{risk}) / (C_{ref}/P_{ref})], SE^2 = [(1/C_{risk}) - (1/P_{risk})] + [(1/C_{ref}) - (1/P_{ref})].$$

The MAC was calculated from the exercise workload at the termination of exercise testing and relative exercise intensity (ie, proportion of the workload to MAC). The exercise workload was converted into MET units (1 MET corresponds to 3.5 mL/min/kg of oxygen consumption [$\dot{V}O_2$]), according to the Metabolic Calculation Handbook by

Figure 1. Selection of Articles for Meta-analysis

CHD indicates coronary heart disease; CRF, cardiorespiratory fitness; CVD, cardiovascular disease; METs, metabolic equivalents; and RRs, risk ratios.

the American College of Sports Medicine.¹⁰ Relative exercise intensity was estimated using a linear equation according to Swain et al¹¹:

$$\text{heart rate at exercise}/\text{maximal heart rate} = 0.64 \times (\text{VO}_2 \text{ at exercise}/\text{maximal VO}_2).$$

For some specific exercise stress tests, the MAC was directly estimated using the prediction equation determined by a previous validation study for each protocol of the exercise test (the Balke treadmill test,^{12,13} the modified Bruce test,¹⁴ and the Canadian Home Fitness test¹⁵).

When exposure was expressed as a range, we converted it into point estimates expressed as average exposure using the midpoint of the range except for the lowest and highest fit group. If data on the average value were not available, it was estimated by the assumption that the MAC levels of the study population had a normal distribution using the mean value and its SD of each study sample. This assumption is consistent with a prior study.¹⁶ However, if the SD was not available, we assumed that its value equaled 2 METs, according to the statement of the American Heart Association.¹⁷

After converting all exposures into MET units, we additionally adjusted MET units for age and sex. According to a Statement for Healthcare Professionals From the American Heart Association,¹⁷ we assumed that the MAC is 2 METs lower in women than in men and that for each year of aging, it decreased by 0.1 MET based on a prior study.¹⁸ Finally, we represented CRF as the adjusted MAC under the assumption that all participants were 50-year-old men in the analyses described below.

Dose-Response and Categorical Analyses

We first performed dose-response analyses by summarizing how much risk reduction could be predicted per incremental increase in CRF. The study-specific RR for each higher MET (corresponding to 1-km/h higher running/jogging speed) in MAC, if not reported, was estimated by regressing the natural logarithm of the RR (lnRR) according to each CRF category against its corresponding mean MAC value, using the method described by Greenland and Longnecker.¹⁹

We then performed categorical analyses to summarize the risk of all-cause mor-

tality and CHD/CVD for low CRF. We assigned every RR reported in each study to 1 of the following 3 comparisons based on the CRF level of risk and reference group: (1) low vs high CRF, (2) low vs intermediate CRF, and (3) intermediate vs high CRF. This method is based on a previous meta-analysis of the relationship between activity level and stroke risk.²⁰ For studies that presented risk estimates for more than 2 CRF categories, the ranges of the adjusted MAC of the lowest, highest, and in-between categories defined by each study were 5.5 to 7.8, 11.0 to 15.2, and 7.9 to 10.7 METs, respectively; except that in 2 studies,^{21,22} the second highest category of CRF was more than 11.0 METs and, in 1 study,⁷ the highest category of CRF was 10.6 METs.

To avoid overlap of the CRF range of the 3 categories, we defined low, intermediate, and high CRF as less than 7.9 METs, 7.9 to 10.8 METs, and 10.9 METs or more, respectively. Consequently, we could assign every RR in each study to 1 of the 3 predefined subgroups with 2 exceptions. In 2 studies,^{21,22} the mean MAC values for both the highest and the second highest category were the same as the high CRF category (defined by ≥ 10.9 METs). Therefore, RR data for comparison between 2 CRF categories could not be included in our categorical analysis for these 2 studies.

Statistical Analysis

The pooled RRs for a 1-MET higher level of MAC and the lower CRF in comparison with the higher CRF within each of the 3 comparisons were estimated by using a fixed-effects or random-effects model.²³ If significant heterogeneity of RRs that was tested by calculating the I² statistic²⁴ was present, we chose the pooled estimates from the random-effects model because it is better than the fixed-effects model and it explains between-study heterogeneity.

To examine the effect of study characteristics on risk reduction per 1-MET higher level of MAC, sensitivity analyses were conducted for the possible confounders (mean age [≥ 50 years or not], sex [only men or not], adjustment for smoking [yes or no], adjustment for multiple confounders, defined as adjustment

for >3 factors among obesity, hypertension, total cholesterol or low-density lipoprotein cholesterol, high-density lipoprotein cholesterol and diabetes [yes or no], mean follow-up [≥12 years or <12 years], instrument for assessing CRF [ergometer or others], and maximal exercise testing [yes or no]. To examine the extent to which between-study heterogeneity was explained by these study characteristics, we additionally conducted linear multiple regression analyses by simultaneously entering these confounders as explanatory variables.

Categorical analyses were repeated with multadjustment for the prespecified confounders to consider the potential heterogeneity of study characteristics among the subgroups (ie, low vs high CRF, low vs intermediate CRF, and intermediate vs high CRF). Tests of interaction were performed to assess whether the association between CRF and the study outcomes varied across these 3 subgroups.

The Begg and Egger tests^{25,26} were used for assessment of publication bias (ie, the tendency for positive associations to be published and negative or null associations to be unpublished). We also followed the Duval and Tweedie “trim and fill” procedure²⁷ as a method of adjustment for suspected publication bias. This method considers the possibility of hypothetical “missing” studies that might exist, imputes their RRs, and recalculates a pooled RR that incorporates the hypothetical missing studies as though they actually existed.

Two-sided $P \leq .05$ was considered statistically significant, except for the test of publication bias for which the recommended levels are $P \leq .10$.²⁸ Data were analyzed using STATA version 10 (STATA Corp, College Station, Texas).

RESULTS

Literature Search and Study Characteristics

FIGURE 1 shows the number of studies that were identified and excluded at dif-

ferent stages of the selection process. A total of 33 studies^{5-9,16,21,22,29-33} were included in our meta-analysis. Characteristics of the 33 selected studies comprising 102 980 participants (range, 486-25 341) and 6910 cases (range, 26-941) for all-cause mortality and 84 323 participants (range, 302-20 278) and 4485 cases (range, 10-1512) for CHD/CVD are shown in TABLE 1. Twenty-one studies* reported all-cause mortality and 24 studies† reported CVD/CHD. Mean age and follow-up duration ranged from 37 to 57 years and 1.1 to 26 years, respectively. Eight studies^{8,33,37,39,45,46,49,52} were used for the dose-response analyses only and 4 studies^{9,16,40,44} were used for the categorical analyses only. In 20 studies,‡ RRs were adjusted for smoking and in 9 stud-

 ‡References 5, 7-9, 16, 21, 22, 30, 32, 33, 37-39, 44-46, 48, 50, 52, 53.

ies,^{7-9,16,33,39,46,50,52} there were multiple study confounders (available in an eTable [http://www.jama.com]).

Dose-response Analyses

FIGURE 2 shows the pooled estimates for the reduction in risk of all-cause mortality and CHD/CVD per higher MET of exercise capacity. Pooled RRs of all-cause mortality and CHD/CVD per 1-MET higher level of MAC were 0.87 (95% CI, 0.84-0.90) and 0.85 (95% CI, 0.82-0.88), respectively. There was evidence of statistical heterogeneity of RRs across studies ($I^2=82.3\%$; $P<.001$ for all-cause mortality; $I^2=74.7\%$; $P<.001$ for CHD/CVD).

TABLE 2 shows the results of analyses investigating the associations of study characteristics on each outcome. The finding of risk reduction per higher MET for all-cause mortality and CHD/CVD was consistently significant in all of the stratified analyses. However, studies with a follow-up of at least 12 years had weaker associations with study outcomes compared with those that had follow-up of less than 12 years for all-cause mortality ($P=.08$) and CHD/CVD events ($P=.004$). The associations between CRF and risk of CHD/CVD events were stronger in studies that used an ergometer for assessing CRF ($P=.009$) or conducted maximal exercise testing ($P=.02$) and were weaker in studies that were adjusted for smoking ($P=.006$) or multiple metabolic factors ($P=.06$). However, these study characteristics did not influence the associations between MAC and risk of all-cause mortality.

Multiple regression analyses in which all the study characteristics listed in Table 2 were entered as independent variables indicated that study characteristics significantly explained the heterogeneity of the RRs per 1-MET higher level of MAC (all-cause mortality, 79% of total variance; $P=.01$; and CHD/CVD, 67% of total variance; $P=.01$). After adjustment for these study characteristics, there were neither significant differences in risk estimates of CHD/CVD between CHD and CVD (0.89; 95% CI, 0.86-0.92 and 0.89; 95%

CI, 0.87-0.90, respectively; $P=.99$) nor between CHD or CVD death and CHD or CVD events (0.88; 95% CI, 0.86-0.90 and 0.90; 95% CI, 0.88-0.91, respectively; $P=.27$).

Categorical Analyses

We performed categorical analyses to summarize the risk of all-cause mortality and CHD/CVD for 3 subgroups (low vs high CRF [FIGURE 3], low vs inter-

Figure 2. Meta-analysis of All-Cause Mortality and CHD/CVD per 1-MET Higher Level of MAC

CHD indicates coronary heart disease; CI, confidence interval; CVD, cardiovascular disease; MAC, maximal aerobic capacity; MET, metabolic equivalent; RR, risk ratio. Area of each square is proportional to study weight.

mediate CRF [FIGURE 4], and intermediate vs high CRF [FIGURE 5]). After adjustment for heterogeneity of study characteristics and compared with high and intermediate CRF, respectively, the pooled RRs for the association of low CRF with all-cause mortality were 1.70 (95% CI, 1.51-1.92) and 1.56 (95% CI, 1.39-1.75), respectively. After adjustment for heterogeneity and compared with high and intermediate CRF, respectively, the pooled RRs for the association of low CRF with CHD/CVD events were 1.40 (95% CI, 1.32-1.48) and 1.47 (95% CI, 1.35-1.61), respectively. The pooled RRs for the associations of intermediate CRF with all-cause mortality and CHD/CVD events compared with high CRF were 1.13 (95% CI, 1.04-1.22) and 1.07 (95% CI, 1.01-1.13), respectively. However, tests of the interaction indicated that these estimates for comparisons between intermediate and high risk were significantly lower than for those between low

vs high CRF and low vs intermediate CRF ($P < .001$ for any comparisons). Tests of interaction also indicated that there were no significant differences in risk estimates for low vs high CRF compared with low vs intermediate CRF (all-cause mortality, $P = .28$; CHD/CVD, $P = .33$).

Publication Bias

In risk estimates per 1-MET higher level of MAC, there was a statistically significant publication bias according to Egger test (all-cause mortality, $P = .002$; CHD/CVD, $P = .02$). However, adjustment for publication bias by the trim and fill procedure could not detect hypothetical negative unpublished studies that could influence the study. In some of the categorical analyses, statistically significant publication bias was also observed in risk estimates after adjustment for heterogeneity of study characteristics (pooled RR of all-cause mortality for low vs high CRF and low vs intermediate

CRF, $P = .03$ by Egger test and $P = .03$ by Begg test, respectively; pooled RR of CHD/CVD for low vs intermediate CRF, $P < .001$ by Egger test). After incorporating the hypothetical studies using trim and fill methods, the risk estimates were attenuated in risk of all-cause mortality for low vs high CRF (RR, 1.48; 95% CI, 1.31-1.68) and low vs intermediate CRF (RR, 1.35; 95% CI, 1.18-1.54), and CHD/CVD for low vs high CRF (RR, 1.38; 95% CI, 1.30-1.45), which suggested the existence of potentially negative studies. Nevertheless, these biases did not change the general conclusions.

COMMENT

Our meta-analysis is the first to our knowledge to quantify CRF as measured by METs, which is a standard scale for expressing exercise workload, and its relationship to all-cause mortality and CHD or CVD events in healthy men and women. According to the dose-response analyses, a 1-MET higher level of MAC was as-

^bMeans of adjustment for more than 3 coronary risk factors among obesity (or body mass index or waist-to-hip ratio), systolic blood pressure (or hypertension), total cholesterol (or low-density lipoprotein cholesterol or hyperlipidemia), high-density lipoprotein cholesterol, and diabetes.

sociated with 13% and 15% decrements in risk of all-cause mortality and CHD/CVD, respectively. From the clinical viewpoint, these values may be considerable. For example, based on risk estimates of the components of metabolic syndrome according to the National Cholesterol Education Program,⁵⁴ these findings suggest that a 1-MET higher level of MAC is comparable to a 7-cm, 5-mm Hg, 1-mmol/L, and 1-mmol/L decrement in waist circumference,⁵⁵ systolic blood pressure,⁵⁶

triglyceride level (in men),⁵⁷ and fasting plasma glucose,⁵⁸ respectively, and a 0.2-mmol/L increment in high-density lipoprotein cholesterol.⁵⁹ It is possible that prediction of CHD risk could be improved by including CRF with already established risk factors for CHD.

In categorical analyses, individuals with low CRF (<7.9 METs in MAC) had a substantially higher risk of all-cause mortality and CHD/CVD compared with those with intermediate and high CRF

(7.9-10.8 and ≥10.9 METs in MAC, respectively). These risk estimates were higher than those for individuals with intermediate CRF compared with those with high CRF, according to the test of interaction. These analyses suggest that a minimal CRF of 7.9 METs may be important for significant prevention of all-cause mortality and CHD/CVD. A previous review suggested that physical activity yielding 1000 kcal energy expenditure per week is needed for signifi-

Figure 3. Meta-analysis of All-Cause Mortality and CHD/CVD for Individuals With Low vs High CRF

CHD indicates coronary heart disease; CI, confidence interval; CRF, cardiorespiratory fitness; CVD, cardiovascular disease; MET, metabolic equivalent; NA, not available; RR, risk ratio. Low and high CRF categories were defined as less than 7.9 METs and 10.9 METs or more of maximal aerobic capacity, respectively, under the assumption that all participants were 50-year-old men. Crude and adjusted RR indicate RRs before and after adjustment for study heterogeneity among the subgroups, respectively.

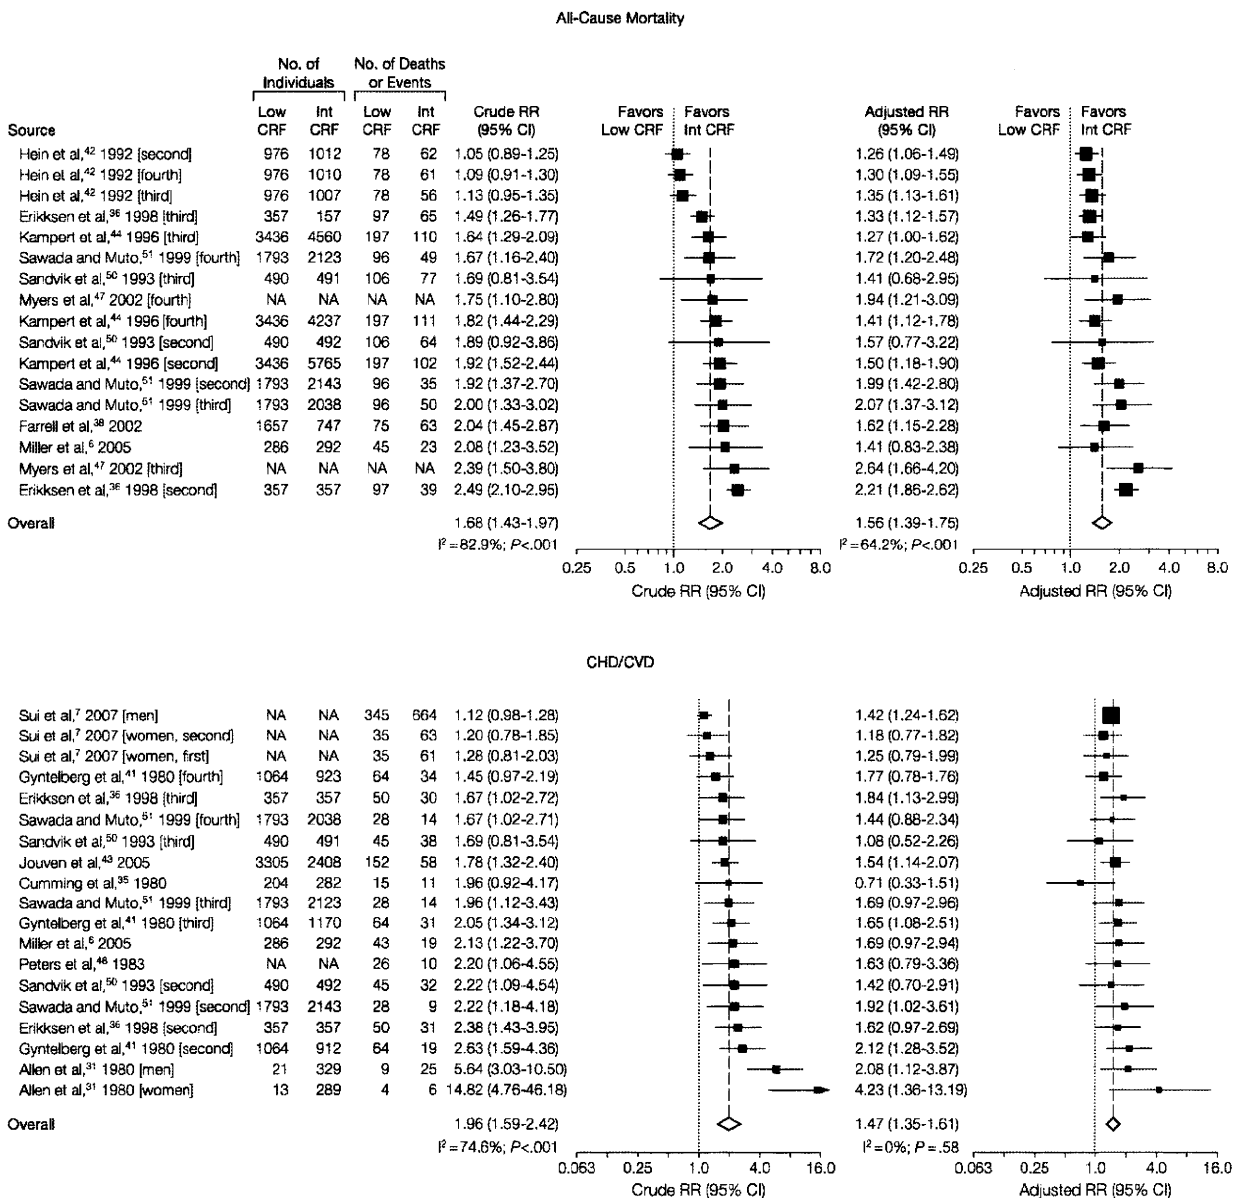

cant risk reduction of all-cause mortality.⁶⁰ However, using CRF may be preferable to using physical activity as risk predictors because 1 prior study⁶¹ suggested that physical fitness was more

strongly correlated with CHD than physical activity.

According to the results reported herein, the minimum CRF level that is associated with significantly lower event

rates for men and women is approximately 9 and 7 METs (at 40 years old), 8 and 6 METs (at 50 years), and 7 and 5 METs (at 60 years), respectively. This means that women and men younger than 60 years

Figure 4. Meta-analysis of All-Cause Mortality and CHD/CVD for Individuals With Low vs Intermediate CRF

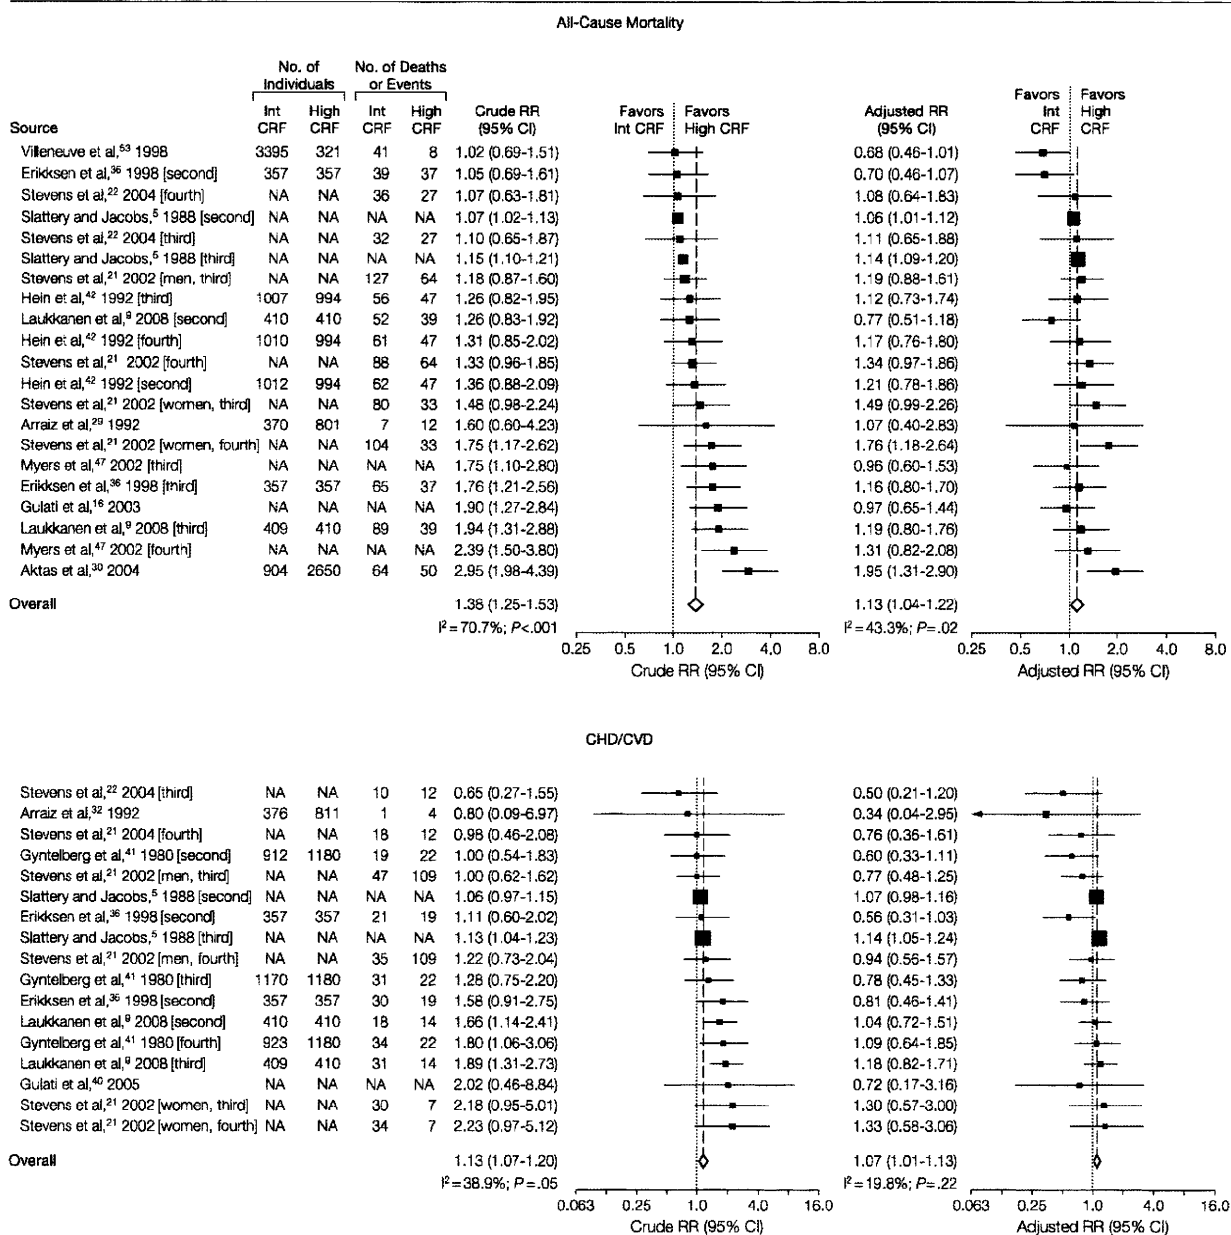

CHD indicates coronary heart disease; CI, confidence interval; CRF, cardiorespiratory fitness; CVD, cardiovascular disease; Int, intermediate; MET, metabolic equivalent; NA, not available; RR, risk ratio. Low and intermediate CRF categories were defined as less than 7.9 METs and 7.9 to 10.8 METs of maximal aerobic capacity, respectively, under the assumption that all participants were 50-year-old men. Crude and adjusted RR indicate RRs before and after adjustment for study heterogeneity among the subgroups, respectively. The words first, second, third, and fourth in brackets represent comparisons between the lowest CRF category and the highest, second, third, or fourth CRF category in the relevant study.

would need to complete stage I (1.7 mph at gradient 10°) and stage II (2.5 mph at gradient 12°), respectively, of the standard Bruce protocol, which is one of the most

commonly used treadmill tests in clinical settings.¹⁴ If the CRF level is expressed in terms of walking speed, men around 50 years of age must be capable of con-

tinuous walking at a speed of 4 mph and women must continuously walk at 3 mph for prevention of CHD,¹⁷ with the assumption that the anaerobic threshold is 50%

Figure 5. Meta-analysis of All-Cause Mortality and CHD/CVD for Individuals With Intermediate vs High CRF

CHD indicates coronary heart disease; CI, confidence interval; CRF, cardiorespiratory fitness; CVD, cardiovascular disease; Int, intermediate; MET, metabolic equivalent; NA, not available; RR, risk ratio. Intermediate and high CRF categories were defined as 7.9 to 10.8 METs and 10.9 METs or more of maximal aerobic capacity, respectively, under the assumption that all participants were 50-year-old men. Crude and adjusted RR indicate RRs before and after adjustment for study heterogeneity among the subgroups, respectively. The words second, third, and fourth in brackets represent comparisons between the second, third, or fourth highest CRF category and the highest CRF category in the relevant study.

to 60% of MAC.⁶² It is possible that consideration of low CRF as a major coronary risk factor could be put into practical use in the clinical setting through identification of low exercise tolerance by exercise stress testing or in daily life by the speed at which a person can walk before experiencing exhaustion.

Some cross-sectional population studies have suggested that higher aerobic fitness is associated with more favorable coronary or cardiovascular risk factor profiles^{63,64}; therefore, the association between CRF and the risk of all-cause mortality and CHD/CVD could potentially be explained by residual confounding by established risk factors. Our sensitivity analyses indicated that a weaker association was observed between a 1-MET higher level of MAC and risk reduction of CHD/CVD, but not all-cause mortality, in studies with adjustment for smoking or more comprehensive risk factors. This finding suggests that better CRF is independently associated with longevity, while the inverse association between CRF and risk of CHD/CVD is explained partly by established coronary risk factors.

Limitations of this meta-analysis must be considered. First, a possible misclassification bias might affect our results. Misclassification bias could occur in transforming the reported CRF data into MET units. However, all of the prediction equations used in our analyses for estimating MAC have already been validated and are commonly used. Another possible misclassification bias is due to the fact that the definitions of low, intermediate, and high CRF were fundamentally based on study-specific CRF classifications, which varied from study to study but were not based on a standard cutoff. Fortunately, we could assign every exposure in each study to 1 of the 3 categories, which did not overlap with few exceptions, although MAC values in each category are approximately 1 MET smaller than those based on a general standard (eg, data from the National Health and Nutrition Examination Survey⁶⁵). Therefore, the possibility of misclassification bias due to those 2 rea-

sons should be limited. Second, Begg or Egger tests suggested publication bias. However, trim and fill analyses to incorporate potentially existing negative studies did not change the general result, although the risk estimates were moderately attenuated. Nevertheless, this possibility was not fully excluded by this analysis.

Based on the findings of our meta-analysis, we suggest for future research (1) further development of a CHD prediction algorithm (eg, Framingham Scores⁶⁶) that would consider both CRF and the classical coronary risk factors to allow physicians to use CRF as a major risk factor in clinical settings; (2) cost-effectiveness of exercise testing for assessing CRF from the viewpoint of primary prevention of all-cause mortality and CHD; and (3) a clinical trial to determine whether an intervention that improves CRF by exercise reduces the risk of all-cause mortality and CHD.

In conclusion, better CRF was associated with lower risk of all-cause mortality and CHD/CVD. A 1-MET higher level of MAC was associated with a 13% and 15% risk reduction of all-cause mortality and CHD/CVD, respectively. The minimal MAC value for substantial risk reduction in persons aged 50 (SD, 10) years was estimated to be 8 (SD, 1) METs for men and 6 (SD, 1) METs for women. We suggest that CRF, which can be readily assessed by an exercise stress test, could be useful for prediction of CHD/CVD and all-cause mortality risk in a primary care medical practice.

Type 2 diabetes

ABSTRACT

Aim: To investigate the efficacy of continuing glimepiride in combination with basal–prandial insulin therapy in type 2 diabetes.

Methods: An open crossover study was performed with arms of discontinuation and continuation of glimepiride in 25 subjects with mean diabetes duration of 17 years and 5 years of insulin treatment combined with glimepiride plus metformin. At entry and at the end of each 3-month arm, meal tolerance tests were performed for measurements of blood glucose and C-peptide.

Results: In terms of between-treatment differences (discontinuation vs. continuation arm of glimepiride) during meal tolerance tests performed at the ends of arms, significant increases in plasma glucose were seen on the discontinuation arm at 0-, 30-, and 60-min, while significant decreases in serum C-peptide were observed at 60- and 120-min. A1C values of the discontinuation arm significantly increased (from 6.6 ± 0.6 at baseline to 7.7 ± 0.8 at 3-months, $p < 0.0001$). Increases in A1C were closely correlated with decreases in area under the curve of meal-stimulated serum C-peptide ($r = -0.61$, $p < 0.0001$).

Conclusions: Since endogenous insulin secretion is more physiological than subcutaneous insulin injection, continuing glimepiride may remain beneficial, partly through enhancing insulin secretion, in individuals with a long duration of diabetes and basal–prandial insulin therapy.

1. Introduction

Whether one should continue the use of sulfonylurea (SU) in subjects who have started and/or maintained insulin therapy still remains uncertain [1–4]. Examining the advantages and limitations is thus highly important. Some experts may discontinue the use of SU. Several older review papers [2–4] and original studies [5–7] were not necessarily in favor of the use of SU in combination with insulin. SU may affect

overload stimulation of insulin secretion to B-cells and may accelerate apoptotic B-cell death [8]. Other experts, albeit the majority, continue the use of SU when starting insulin therapy. Several reports have supported SU-combined insulin therapy since it leads to better glycemic control than insulin alone [1,9–14]. However such studies involved older medications such as glibenclamide (or glyburide) [5–7,13,14], glipizide [7,11,14], or chlorpropamide [11,13], with ultralente, NPH, or premixed insulin [5–7,11–14], and the

doi:10.1016/j.diabres.2010.10.007

achieved metabolic control as measured by glycosylated hemoglobin A1C (A1C) has not been satisfactory, i.e., over 8.0%. Glimepiride is a new third-generation SU, which has an equivalent hypoglycemic effect to that of glibenclamide. It can improve both insulin secretion and peripheral insulin sensitivity [15–17]. A recent new concept of physiological basal–prandial insulin replacement has led to the development of analogue insulin including prandial rapid-acting insulin and insulin glargine. Glargine is a long-acting insulin with a more favorable 24-h time-action profile having no pronounced peak and less hypoglycemia than conventional long- or intermediate-acting insulins [18]. It is important to investigate the optimal treatment for maintaining near-normal glycemia since it could prevent microvascular and macrovascular complications.

Although these new medications of glimepiride and basal–prandial insulin therapy have been developed, no studies have investigated whether glimepiride should be continued in individuals receiving basal–prandial insulin. It remains unclear whether the endogenous insulin secretion, as measured by serum C-peptide, should be enhanced by glimepiride to sustain good glycemic control under basal–prandial insulin treatment. The aim of the present study was to investigate the efficacy of continuing glimepiride in subjects with type 2 diabetes. We performed an open crossover study with arms of discontinuation and continuation of glimepiride, and investigated the physiological mechanism underlying the benefits of the combination therapy.

2. Research design and methods

2.1. Subjects

We investigated 25 subjects with type 2 diabetes who fulfilled the following inclusion and exclusion criteria. Subjects had type 2 diabetes of at least 5 years' known duration, were aged at least 40 years, and had negative tests for anti-GAD antibody (GADAb Cosmic, Tokyo, Japan) without any episodes of ketoacidosis, BMI ≤ 40 kg/m², and A1C level $\leq 8.0\%$ with three-time injections of premeal insulin, one insulin glargine in the morning, glimepiride 6 mg before breakfast, and metformin 750 mg. Glimepiride 6 mg and metformin 750 mg are the maximum doses allowed in Japan. Subjects with A1C $>8.0\%$ were not included since excessive hyperglycemia would have limited the sensitivity of the SU-withdrawal procedure. They had had a poor glycemic control (A1C level $>8\%$) despite maximal dose of SU, glibenclamide 10 mg/day or glimepiride 6 mg/day, together with metformin (750 mg/day) in addition to diet and exercise therapy. They had been treated with insulin therapy including human rapid and NPH insulin, and all subjects had been treated for at least one year with basal–prandial insulin therapy using rapid-acting insulin (aspart/lispro) at each meal (as prandial insulin) and insulin glargine in the morning with continuing glimepiride 6 mg/day and metformin 750 mg/day. Titration of insulin dose and the algorithm, and shifting of the insulin-regimen from NPH to glargine were performed as previously described [19]. Subjects with impaired hepatic, renal, or cardiac function

Fig. 1 – Study design of open crossover study. Dotted lines indicate periods when glimepiride was withdrawn. Meal tolerance tests (MTT) were performed four times, and glycosylated hemoglobin was measured up to 6 months after the discontinuation/continuation arms of glimepiride were completed.

or recurrent major hypoglycemia were excluded. All subjects gave written informed consent, and the study was approved by the ethical committee and carried out in accordance with the Helsinki Declaration II.

2.2. Methods

Fig. 1 shows the study design of the open crossover study. After an initial meal tolerance test (MTT) in which all subjects took glimepiride before the meal, together with metformine and rapid-acting/glargine insulin, each subject was randomized to either the continuation or discontinuation arm of glimepiride. At the end of the 3-month arm, the second MTT was performed and thereafter glimepiride was restarted in patients on the discontinuation arm. Six months after the second MTT, each patient was crossed over to the alternative treatment arm. The third and fourth MTTs were done at the start and end of the 3-month period. In order to assess the contribution of glimepiride to the concurrent insulin therapy, the insulin dose/regimen was fixed throughout the study.

MTT was performed after an overnight fast (more than 12 h). A pre-specified breakfast was prepared for the test, containing carbohydrate 63.8 g, protein 24.6 g, fat 11.0 g, sodium 1.2 g, and a total of 466 calories. Blood samples were drawn before and after 30-min, 60-min, and 120-min. The plasma glucose concentration was measured by the glucose oxidase method. The A1C was measured by high-performance liquid chromatography (normal range, 4.3–5.8%) standardized by the Japan Diabetes Society and was certified by the American National Glycohemoglobin Standardization Program (NGSP = $1.019 \times \text{JDS} + 0.30$). Serum C-peptide concentration was measured by radioimmunoassay using a C-PEPTIDE RIA kit (Shionogi, Osaka, Japan). The interassay variation coefficients were 5–8% for all assays.

Hypoglycemia was defined as any episode in which clinical symptoms were confirmed or blood glucose level was confirmed <3.3 mmol/l (60 mg/dl). Hypoglycemia was considered minor when the episodes were self-treated by the patients, and as major when the episode required any kind of external help.

2.3. Statistical analysis

Results are given as mean ± SD. Differences between relevant groups were tested by the Student's unpaired t-test or paired t-test for continuous variables with Bonferroni corrections for multiple comparisons. Comparisons among the three groups were performed using one way analysis of variance. The chi-squared test was used for discrete variables. Between-treatment difference of A1C was explored by the ANCOVA test, with treatment group as a fixed effect and sex, age, duration of diabetes, BMI, and baseline values of total insulin dose, A1C, fasting plasma glucose, and fasting C-peptide as covariates to compare within-subject treatment differences. Pearson's coefficient was used to analyze the correlation between two continuous variables. *p*-Values under 5% (two-tailed) were considered to be significant. All analyses were performed with the statistical software package SPSS (Dr SPSS II version, SPSS Japan Inc., Tokyo, Japan).

3. Results

The clinical characteristics of the subjects at baseline are shown in Table 1. The insulin dose, a mean of 15 units of prandial and 12 units of glargine, was unchanged throughout the study, together with 750 mg of metformin. Baseline values of plasma glucose and C-peptide during the MTT were similar between arms of discontinuation and continuation of glimepiride (Fig. 2A). Baseline values of A1C had no association with the fasting or prandial C-peptide levels. In terms of the between-treatment differences (discontinuation vs. continuation arm) during the MTT performed 3-months after randomization, significant increases in plasma glucose were seen in the discontinuation arm at 0-, 30-, and 60-min (Fig. 2B), while significant decreases in serum C-peptide were observed at 60- and 120-min (Fig. 2). Similarly, when compared to the baseline values in the discontinuation arm (i.e., just before the discontinuation of glimepiride), significant increases in plasma glucose at 0- and 30-min and decreases in serum C-peptide at 30-, 60-, and 120-min were seen after 3-month discontinuation of glimepiride. Accordingly, the A1C values of the discontinuation arm significantly increased (from 6.6 ± 0.6

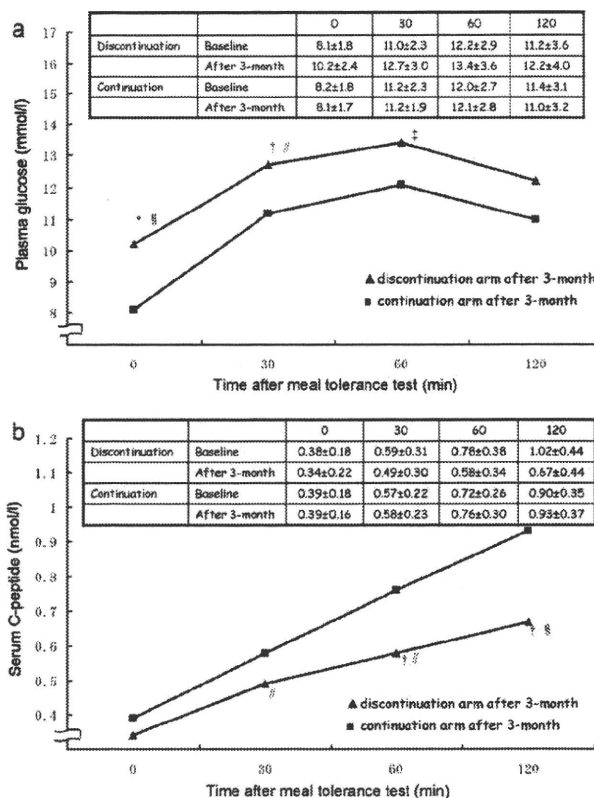

Fig. 2 – Plasma glucose values (A) and serum C-peptide values (B) during meal tolerance tests (MTT) before and 3-months after randomization into discontinuation or continuation of glimepiride. The lines indicate discontinuation (G-) and continuation (G+) after 3-months. **p* < 0.001, †*p* < 0.01, ‡*p* < 0.05 vs. continuation at 3-months. §*p* < 0.0001, ||*p* < 0.01 vs. the baseline.

at baseline to 7.7 ± 0.8 at 3-month, *p* < 0.0001), compared with those of the continuation arm throughout the three-month period (Fig. 3). These values returned to the baseline values three months after restarting glimepiride.

To investigate what factors at baseline are associated with a subsequent increase in A1C after withdrawal of glimepiride, predictors for 3-month changes in A1C were sought in the discontinuation arm. While changes in A1C had no significant associations with baseline values of A1C (*r* = 0.01, *p* = 0.50), total insulin dose (*r* = 0.06, *p* = 0.39), duration of diabetes (*r* = -0.35, *p* = 0.09), treatment period with SU (*r* = -0.10, *p* = 0.64), fasting C-peptide (*r* = 0.28, *p* = 0.11), increment of C-peptide during the first 30-min (*r* = 0.35, *p* = 0.09), and area under the curve (AUC) of C-peptide during meal tolerance tests (*r* = 0.27, *p* = 0.08), only BMI (*r* = 0.46, *p* = 0.02) was significantly associated. Changes in A1C also had no significant associations with 3-month values of fasting C-peptide (*r* = 0.13, *p* = 0.53) and AUC of C-peptide during meal tolerance tests (*r* = 0.02, *p* = 0.90). We found, however, that increases in A1C including both arms were closely correlated with decreases in AUC of serum C-peptide during the MTT (*r* = -0.54, *p* < 0.0001), and were more closely correlated with decreases of incre-

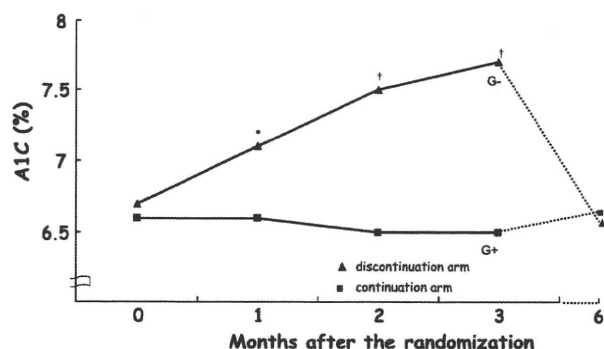

Fig. 3 – A1C values after assignment into discontinuation or continuation of glimepiride. * $p < 0.001$, † $p < 0.0001$ vs. continuation at the same month.

mental serum C-peptide after the meal ($r = -0.61$, $p < 0.0001$, Fig. 4). The correlation coefficient was -0.45 ($p = 0.03$) when limited to the discontinuation arm.

Since the duration of diabetes varied widely, the results of A1C values and serum C-peptide values before and after discontinuation of glimepiride (in the discontinuation arm) were analyzed by the tertiles of duration of diabetes. Fasting and post-meal serum C-peptide levels tended to be lower in the groups of longer duration, however, the differences did not reach the statistical significance. The three groups, i.e., short (<13 year, $n = 9$), middle (13–17 year, $n = 8$), and long (>17 year, $n = 8$) duration of diabetes, exhibited similar worsening of A1C after discontinuation of glimepiride (6.6 ± 0.8 – 7.7 ± 0.9 , 6.6 ± 0.4 – 7.8 ± 0.9 , 6.7 ± 0.6 – $7.6 \pm 0.8\%$, respectively $p < 0.01$). Significant falls in post-meal C-peptide (120-min) after discontinuation of glimepiride were observed in each three group (1.22 ± 0.51 – 0.85 ± 0.45 , 1.02 ± 0.37 – 0.68 ± 0.51 , and 0.79 ± 0.33 – 0.48 ± 0.29 mmol/l, respectively, $p < 0.05$).

Incidences of minor hypoglycemia (episodes per person-month) between discontinuation and continuation arms were 0.23 vs. 0.21 during the three months prior to the assignment ($p = 0.99$), 0.04 vs. 0.12 during the assigned 3-months ($p = 0.13$), and 0.16 vs. 0.27 thereafter ($p = 0.16$). No major hypoglycemia

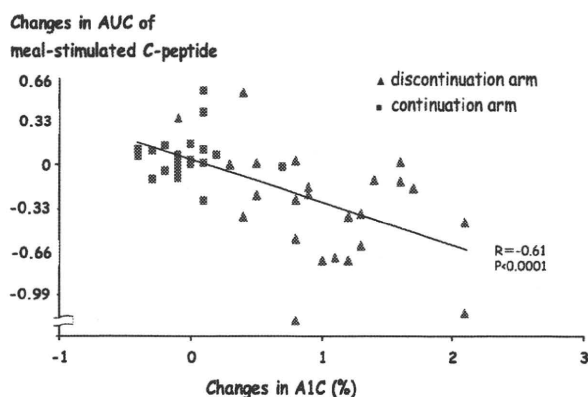

Fig. 4 – Correlation between changes in A1C during 3-month randomization and concurrent changes in the area under the curve (AUC) of meal-stimulated C-peptide.

occurred. Changes in body weight (kg) between discontinuation and continuation arms were -1.2 ± 1.0 vs. -0.7 ± 1.1 during the assigned 3-month period ($p = 0.09$), and 0.8 ± 1.4 vs. 0.7 ± 1.7 thereafter ($p = 0.87$).

4. Discussion

We performed an open, crossover study to assess the contribution of glimepiride to metabolic control in subjects with type 2 diabetes who were relatively well controlled with physiological basal-prandial insulin replacement. Our findings indicated that the effects of glimepiride did not decline severely after more than 10 years of diabetes. While not a few studies have examined the use of SU in combination with insulin (as reviewed in [1–4,9,10]), the notable features in the present study and the distinct differences from the previous reports were as follows. (1) Subjects had been treated with insulin for a mean of five years, while most previous studies were done when initiating insulin therapy [5–7,11–13]. Known duration of diabetes of 17 years in our study was longer than in any other reports [5–7,11–13], and responses to discontinuation of glimepiride were shown according to groups with different durations of diabetes. (2) Most studies included one or two insulin injections [5–7,11–13], while basal-prandial insulin therapy including multiple (four times) injections, i.e., intensive insulin therapy, has never been investigated. (3) Older generation SUs were used previously and glimepiride was investigated in only one study [12]. (4) The baseline A1C of 6.6% is the lowest, compared with 8–9% or more in other studies [5–7,12–14]. (5) Studies employing crossover design and MTT have rarely been conducted [20,21].

The UK Prospective Diabetes Study showed that early addition of ultralente injection once in subjects with a mean A1C of 6.9% on maximal dose of SU reduced and maintained the A1C over six years to a median of 6.6%, which was significantly lower than the median of 7.1% in subjects with insulin alone [11]. This indicated the usefulness of SU when initiating insulin, but did not clarify whether the use of SU should be continued thereafter. Nybäck-Nakell et al. indicated the usefulness of continuing SU in subjects with long duration of SU plus insulin treatment by demonstrating worsening of fasting plasma glucose after SU withdrawal [14]. There was a small pilot study that included subjects who used various kinds of SU and insulin and whose follow-up times varied. Our findings, supported by these studies, extend this issue further.

Stenman et al. performed the MTT [20] and found that fasting plasma glucose concentrations were improved more than postprandial glucose concentrations by adding glibenclamide to insulin (one dose of intermediate-acting insulin) using a crossover design. Schade et al. also showed improvement of concentrations in fasting plasma glucose, but not post-challenge glucose after oral glucose tolerance test, through a crossover design of adding glyburide to insulin [21]. These glucose profiles are consistent with our findings, and it is likely that the use of SU influences fasting more than postprandial plasma glucose concentrations. The effect of SU on improving fasting plasma glucose may be explained by its suppression of hepatic glucose production either directly or by stimulation of insulin secretion [22].

It should be noted that the doses of insulin were unchanged in our study. Insulin doses in most of the previous reports were reduced due to the improvement of metabolic control by adding SU [7,11,12,20]. Some showed concomitant increases in fasting C-peptide levels [18,19], which were not found in our study. This may be partly due to the reduction of insulin dose enhancing SU-stimulated fasting C-peptide, since it is known that exogenous insulin can inhibit endogenous insulin secretion [23].

Unfortunately we failed to find any significant baseline variables predictive for individual response to glimepiride with basal–prandial insulin therapy, except for BMI. More obese subjects exhibited worsening of A1C after glimepiride withdrawal. Glimepiride is reported to have an extrapancreatic effect [16]. However, the extrapancreatic effect of glimepiride was uncertain in the present study because no correlations were found between BMI and C-peptide and/or insulin dose (data not shown). Future studies will be necessary to clarify this effect.

Overall, the frequencies of hypoglycemia and weight gain were very small compared with previous studies [5–7,11–13,20], whereas hypoglycemia tended to be lower during the discontinuation period. This may partly be due to the development of insulin analogues that mimic physiologic basal–prandial insulin secretion, together with the use of metformin. Regarding the cost, glimepiride 6 mg plus insulin 40 units (basal 20 units and prandial 20 units), for instance, costs 1522 US dollars per year for a patient. SU may reduce the insulin dose by approximately 30% or more [11,12], and thus the corresponding insulin dose of 58 units (basal 28 units and prandial 28 units) without glimepiride costs 1616 US dollars per year for a patient. Therefore at least, the combination therapy may not be inferior to insulin alone in terms of economic benefits.

We believe that combined use of glimepiride is preferable to insulin alone, since secreted endogenous insulin firstly passes through the portal vein and liver, which is in distinct contrast to subcutaneously injected insulin. Combined use of glimepiride, or SUs generally, may potentially enhance the stabilizing effects of remaining endogenous insulin, leading to a reduction of risk for exogenous insulin-induced hypoglycemia at a given level of glycemic control [1,9,24]. Even if the equivalent excellent control could be achieved through sufficient quantity and adequate timing of injected insulin, enhancement of insulin secretion by adding SUs with smaller doses of insulin injection would be more physiological. Alternatively, we should acknowledge that our study needs to be extended and requires an intervention study, in which subjects are randomized to continue the present regimen with glimepiride or to withdraw glimepiride and make any necessary changes in insulin dose to maintain glycemic control. The comparison of glycemic control, weight gain, and frequency of hypoglycemia may validate the usefulness of glimepiride in combination.

Some limitations of our study need to be mentioned. The effect of glimepiride on metabolic control in individuals with type 2 diabetes and insulin therapy found in our study cannot be generalized to those with very low insulin secretion, with seriously poor metabolic control or with extreme obesity, although endogenous insulin secretion is preserved in most subjects with type 2 diabetes. We were unable to find any

predictive factors at baseline for the efficacy of glimepiride, although the baseline values of duration of diabetes, fasting C-peptide, increment of C-peptide during the first 30-min, and AUC of C-peptide during MTT showed borderline statistical significance. Our finding that incremental meal-stimulated C-peptide response to glimepiride was related to better A1C is supported by others [1] and gives an insight into the physiology underlying the observed effect. However, more detailed evaluations for insulin secretion and sensitivity, such as glucose clamp and 24-h profile for C-peptide and blood glucose, and greater numbers of subjects may be necessary in future studies to elucidate this issue. Finally, the question of whether a medium or low dose of glimepiride could also be effective needs further study.

In conclusion, our findings indicated the efficacy and usefulness of maintaining use of glimepiride in combination with basal–prandial insulin therapy, even for subjects with a long duration of diabetes and insulin treatment, at least in part through the enhancement of endogenous insulin secretion.

糖尿病診療マニュアル

能登 洋

国立国際医療研究センター病院糖尿病・代謝症候群診療部

日本糖尿病学会による『科学的根拠に基づく診療ガイドライン』、『糖尿病治療ガイド』の内容は包括的であるが具体性に乏しく実用性が低い。また、エビデンスの批評が甘く、誤用や寄せ集めに終わっていることが少なくない。そもそもEvidence-Based Medicine (EBM)に則ったガイドラインを標榜しておきながら、血糖管理目標では「優・良・可・不可」という患者さんの人格を否定しかねない反EBMの評価呼称を採用して矛盾している。さらに「優」カテゴリーでは死亡が増加する可能性もあり(図1)混乱を招く。

そこで当センターでは糖尿病戦略等研究事業の一環として、ガイドラインを実用化するために妥

当性の高いエビデンスを一義的に重視してそれに立脚した一般診療所・クリニック向けの糖尿病診療マニュアルを作成し、当診療部のホームページで公開した(図2)。その特長は次の通りである。

- ・検査の頻度や選択薬剤の優先度を明記
- ・専門医・拠点病院への紹介の適応とタイミングを記載(病診連携推進)
- ・診療効果の確実性と安全性を重視
- ・100件以上のエビデンスの批評・査定による推奨
- ・インターネットで一般公開中
