been treated previously for HCV infection ($P < 0.001$). Patients in the double-wild group had significantly lower gamma-glutamyl transpeptidase (γ-GTP) levels ($P = 0.032$).

Progress of Patients

The progress of patients in this study is shown in Figure 1. Of the 187 patients, 183 completed 4 weeks of treatment. Among them, 133 were assessed based on HCV RNA dynamics between baseline and week 4. Those completing 12 weeks of treatment totaled 181, of which 154 were assessed for HCV RNA dynamics between baseline and week 12. Those completing 24 weeks of treatment totaled 153, and all were assessed for HCV RNA quantitatively or qualitatively at week 24. Those completing 48 weeks of treatment totaled 114. These 114 patients and the 55 patients who had discontinued treatment because of treatment failure entered a follow-up period. Among these 169 patients, 164 completed 24 weeks follow-up and the sustained virological response (SVR) rate

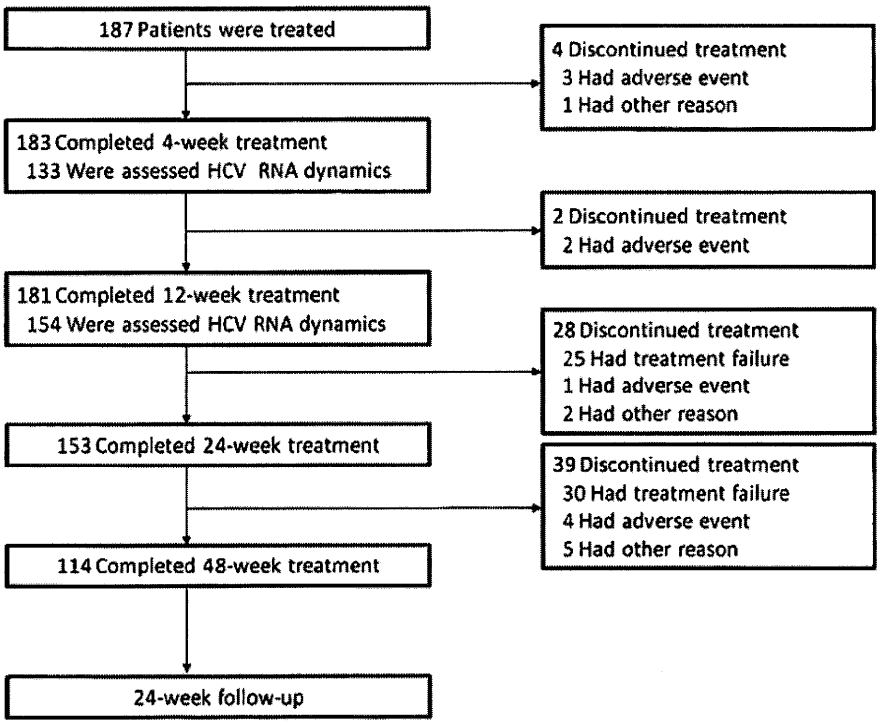

Fig. 1. Treatment and follow-up of the study patients. Treatment was discontinued for patients with <2 log decrease from the baseline HCV RNA level at week 12 or detectable HCV RNA at week 24.

TABLE II. Multivariate Analysis for Factors Associated With <1 log Decrease in HCV RNA Level at Week 4, <2 log Decrease at Week 12, Detectable HCV RNA at Week 24, and Relapse After Treatment

Factor	Category	Odds Ratio	95% CI	*P* value
HCV RNA <1 log decrease at week 4				
White blood cells ($\times 10^6$/l)	<5,000/5,000≤	—	—	NS
γ-GTP (IU/l)	<40/40≤	—	—	NS
Peg-IFN dose (μg/kg/week)	By 0.1 μg/kg/week	0.80	0.67–0.97	0.020
Core aa 70	Wild/mutant	1/2.80	1.16–6.75	0.022
HCV RNA <2 log decrease at week 12				
γ-GTP (IU/l)	<40/40≤	—	—	NS
Peg-IFN dose (μg/kg/week)	By 0.1 μg/kg/week	—	—	NS
Core aa 70	Wild/mutant	1/2.72	1.09–6.78	0.032
Detectable HCV RNA at week 24				
Platelet ($\times 10^9$/l)	<150/150≤	—	—	NS
γ-GTP (IU/l)	<40/40≤	1/2.46	1.02–5.95	0.045
Core aa 91	Wild/mutant	1/4.11	1.73–9.78	0.001
Relapse after treatment				
Ribavirin dose (mg/kg/day)	By 1 mg/kg/day	0.77	0.60–0.98	0.036
Virological response	Complete early virological response/late virological response	1/23.69	5.44–103.08	<0.001

CI, confidence interval; NS, not significant difference; γ-GTP, gamma-glutamyl transpeptidase; Peg-IFN, pegylated interferon; aa, amino acid.

was 48.2% (79/164), based on per-protocol set. Among the 106 patients who had an end-of-treatment response and completed follow-up, 27 showed relapse during the follow-up period; the relapse rate was 25.5% (27/106).

IMPACT OF CORE-RELAPSE AFTER TREATMENT (TABLE II)

Impact of core aa substitutions on <1 log viral decrease rate at week 4, <2 log at week 12, detectable HCV RNA at week 24, and virological relapse after treatment (Table II).

The impact of core aa substitutions on <1 log viral decrease rate at week 4, <2 log at week 12, detectable HCV RNA at week 24, and virological relapse after treatment (Table II).

The impact of the core aa substitutions on <1 log viral decrease at week 4, which is a predictor of non-sustained virological response; fewer than 5% of patients without 1 log decrease at week 4 had an sustained virological response [McHutchison et al., 2009] was examined. Among the 133 patients who completed 4 weeks of treatment, 31 failed to show a ≥1 log decrease of HCV RNA level at week 4. Univariate analysis for factors associated with <1 log decrease of HCV RNA level at week 4 was performed on the following variables: age, sex, body weight, BMI, history of past IFN therapy, baseline HCV RNA level, histological fibrosis and activity, white blood cell count, red blood cell count, hemoglobin level, platelet count, alanine aminotransferase (ALT) level, γ-GTP level, dose exposure of Peg-IFN and ribavirin, and aa substitutions in the HCV core protein. The results indicated that pretreatment white blood cell count, γ-GTP level, the mean dose of Peg-IFN during the first 4 weeks of treatment and single-spot substitution in the HCV RNA core position at aa 70 contributed to a <1 log decrease of HCV RNA level at week 4. Analysis of these factors by multivariate logistic regression analysis showed that substitution of aa 70 (odds ratio (OR) 2.80, 95% confidence interval (CI) 1.16–6.75, $P = 0.022$) as well as the mean dose of Peg-IFN (OR 0.80, 95% CI 0.67–0.97, $P = 0.020$) was independently associated with viral decline (<1 log) at week 4.

Next, the impact of the core aa substitutions on <2 log viral decrease rate at week 12, which is presently considered to be the most reliable predictor of non-sustained virological response [Fried et al., 2002; Davis et al., 2003] was examined. Among the 154 patients who completed 12 weeks of treatment, 25 failed to show a ≥2 log decrease of HCV RNA level at week 12. Univariate analysis was performed on the same factors in the preceding examination. As a result, pretreatment γ-GTP level, the mean dose of Peg-IFN during the first 12 weeks of treatment and single-spot substitution in the HCV RNA core position at aa 70 contributed to a <2 log decrease of the HCV RNA level. These factors were then analyzed by multivariate logistic regression analysis; only substitution of aa 70 (OR 2.72, 95% CI 1.09–6.78, $P = 0.032$) was found to be independently associated with an insufficient virological response (<2 log HCV RNA decrease from baseline level) at week 12.

The impact of the core aa substitutions on detectable HCV RNA at week 24, which is another non-sustained virological response predictor [Davis et al., 2003] was also examined. Among 153 patients who completed 24 weeks of treatment, 30 still had detectable HCV RNA at week 24. Univariate analysis revealed that pretreatment platelet count, γ-GTP level, and single-spot substitution in the HCV RNA core position at aa 91 contributed to the HCV RNA remaining positive. Multivariate logistic regression analysis, using these factors, indicated that substitution of aa 91 (OR 4.11, 95% CI 1.73–9.78, $P = 0.001$) as well as γ-GTP level (>40 IU/l) (OR 2.46, 95% CI 1.02–5.95, $P = 0.045$) was

independently associated with detectable HCV RNA at week 24.

Next, the factors associated with virological relapse after the treatment was examined. Univariate analysis was performed on the virological response (complete early virologival response or late virological response) in addition to the factors in the preceding examination, revealing the mean dose of ribavirin during the full treatment period and a late virological response, but not aa substitutions (single-spot substitution in the HCV RNA core position at aa 70, $P = 0.467$; aa 91, $P = 0.776$).

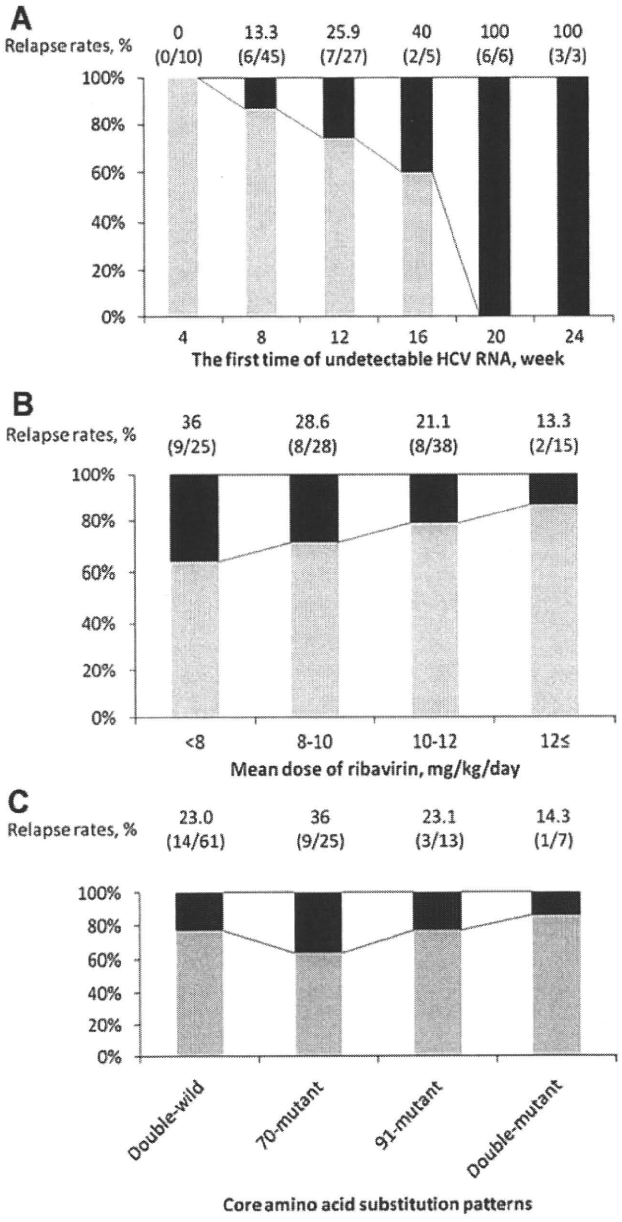

Fig. 2. Relapse rates according to the timing of HCV RNA disappearance (**A**), mean ribavirin dose (**B**), and core amino acid substitution patterns (**C**) in patients who had end-of-treatment response and completed 24-week follow-up. Relapse rates are shown as percentages and the number of patients with relapse in relation to the total number of patients examined is shown at the top of each column. Gray bar, sustained virological response; black bar, relapse.

These factors were analyzed by multivariate logistic regression analysis. This analysis revealed that the mean ribavirin dose (OR 0.77, 95% CI 0.60–0.98, $P = 0.036$) and a late virological response (OR 23.69, 95% CI 5.44–103.08, $P < 0.001$) were independently associated with relapse.

Relapse Rates According to the Timing of HCV RNA Disappearance, Ribavirin Dose, and Core aa Substitution Patterns

The relapse rates were indicated according to the time to the first non-detection of HCV RNA, mean ribavirin dose and core aa substitution patterns (Fig. 2). The relapse rate was 0% (0/10) in patients with undetectable HCV RNA during 1–4 weeks, and increased 13.3% (6/45) during 5–8 weeks, 25.9% (7/27) during 9–12 weeks, 40% (2/5) during 13–16 weeks, 100% (6/6) during 17–20 weeks, and 100% (3/3) during 21–24 weeks (Fig. 2A). Similarly, the relapse rates increased as the mean ribavirin dose decreased; 13.3% (2/15) in patients receiving ≥12 mg/kg/day of ribavirin, 21.1% (8/38) at 10–12 mg/kg/day, 28.6% (8/28) at 8–12 mg/kg/day, and 36% (9/25) at <8 mg/kg/day (Fig. 2B). On the other hand, the relapse rates were similar among the four core aa substitution patterns; 23.0% (14/61) in patients in the double-wild group, 36% (9/25) in 70-mutant group, 23.1% (3/13) in 91-mutant group, and 14.3% (1/7) in double-mutant group (Fig. 2C). In the subgroup of patients receiving <10 mg/kg/day of ribavirin, no significant difference of the relapse rates was observed between double-wild group and 70-mutant and/or 91-mutant group (31.3% (10/32) in double-wild group vs. 33.3% (7/21) in 70-mutant and/or 91-mutant group), and also in the patients receiving ≥10 mg/kg/day of ribavirin (13.8% (4/29) in double-wild group vs. 25% (6/24) in 70-mutant and/or 91-mutant group) (Fig. 3). Among patients with complete early virological response, the relapse rates were also similar between double-wild group and 70-mutant and/or 91-mutant group (13.7% (7/51) in double-wild vs. 18.4% (7/38) in 70-mutant and/or 91-mutant group). The impact of core aa substitutions on relapse rates in patients with late virological response could not be assessed because of the small number of patients.

DISCUSSION

Kobayashi et al. [2010] investigated the clinical and virological factors influencing these core aa substitutions in patients infected with HCV genotype 1 who had not received antiviral therapy, and found that HCV variants with wild type of core aa 70 and 91 significantly decreased with age, while those with the mutant type of core aa 70 and/or 91 significantly increased with age. Furthermore, they demonstrated that the proportion of patients with the mutant type of core aa 70 HCV variant significantly increased with an elevated γ-GTP level and a decrease in platelet counts. In this study, the significant differences of baseline demographics between patient groups according to core aa substitution pat-

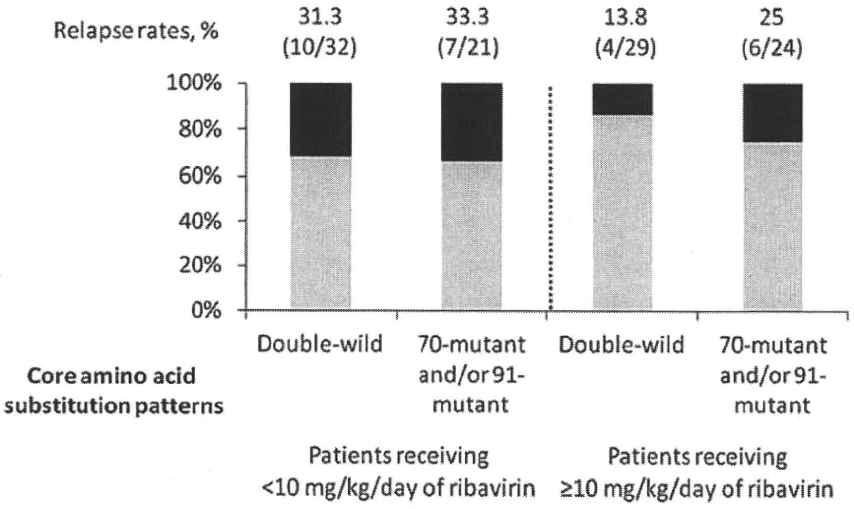

Fig. 3. Relapse rates according to core amino acid substitution patterns in patients receiving <10 mg/kg/day and receiving ≥10 mg/kg/day of ribavirin. Relapse rates are shown as percentages and the number of patients with relapse in relation to the total number of patients examined is shown at the top of each column. Gray bar, sustained virological response; black bar, relapse.

terns were similarly found in age, platelet count, and γ-GTP level. Accordingly, this study cohort had no specific bias and seems to reflect the natural background of the patients according to the HCV variance. In this study, the impact of HCV core aa substitutions on the virological response were evaluated by multivariate analysis, in order to resolve the bias of patient background factors among the groups classified according to the core aa substitution patterns. Recently, Abe et al. [2010] reported that the human genotype of the rs8099917 SNP at the IL28B locus was associated with lower γ-GTP level and viral wild type of core aa 70 and 91. Possibly these differences of IL28B genotype may influence the difference of patient background factors. Further studies are needed to clarify the relationship between human genetic variation and HCV core amino acid substitutions.

The HCV core protein has been reported to have an effect on a variety of cellular functions [Lai and Ware, 2000; Joo et al., 2005; Ariumi et al., 2007; Waris et al., 2007; Osna et al., 2008]. Currently, aa substitutions in the HCV core region has been thought to be related with outcome of antiviral therapy [Akuta et al., 2005; Donlin et al., 2007] and also the development of hepatocellular carcinoma [Akuta et al., 2007a; Hu et al., 2009]. Importance of core aa substitutions, especially at aa 70 and 91, comes to be recognized, and the new method to detect these substitutions easily has been proposed [Nakamoto et al., 2009]. As for the mechanism of antiviral activity on core aa substitutions, Ikeda et al. [2010] showed that core aa substitutions were not associated with intracellular antiviral response to IFN-alpha by in vitro analysis. The mechanism of antiviral activity and hepatocarcinogenesis on core aa substitutions has not been elucidated enough, so far. Further in vitro studies will be needed to clarify this.

Previous studies showed that patients with substitution of core aa 70 often had slow or no decrease in HCV RNA levels during the early phase of IFN-alpha treatment [Akuta et al., 2005, 2007b,c; Donlin et al., 2007]. Consistent with these reports, multivariate analysis in this study revealed that substitution of core aa 70 could be independently associated with insufficient viral decline during the first 12 weeks after the treatment (decline of <1 log from baseline at week 4, <2 log at week 12). This suggests that patients with substitution of core aa 70 are likely to fail to have a sustained virological response. On the other hand, dose exposure of Peg-IFN during the first 4 weeks of treatment was also independently linked to a minimal decline in HCV RNA (<1 log) at week 4 in this study. This suggests that maintaining the dose of Peg-IFN as high as possible until the disappearance of HCV RNA can help avoid treatment failure [McHutchison et al., 2002; Oze et al., 2009], especially in patients with substitution of core aa 70. On the other hand, substitution of core aa 91 was independently associated with detectable HCV RNA at week 24. This suggests that patients with substitution of core aa 91 are likely to achieve non-sustained virological response even if they had a ≥2 log decline in the HCV RNA level at week 12. The reason for the difference of the impact on virological response is not yet clear.

Multivariate logistic regression analysis also showed that the dose exposure of ribavirin during the full treatment period and having late virological response were independently associated with relapse. As for ribavirin exposure, it has been previously demonstrated that the relapse rate among patients responding to the treatment showed a decline in relation to the increase in the dose of ribavirin [Hiramatsu et al., 2009]. In this study, relapse rates were also decreased from 36% to 13.3% with increasing dose exposure of ribavirin among patients with end-of-treatment response. These results

confirm that maintaining a sufficient dose of ribavirin during the full treatment period could reduce the possibility of relapse, and that an extended duration of therapy for patients with late virological response could increase the chance of achieving sustained virological response, regardless of core aa substitution patterns [Berg et al., 2006; Pearlman et al., 2007; Ferenci et al., 2010].

In this study, the COBAS Amplicor HCV Test v2.0, with a lower limit of detection of 50 IU/ml, was used to assess the serum HCV RNA. Recently, real-time PCR-based HCV RNA assays with a higher sensitivity, COBAS TaqMan HCV assay (Chugai-Roche Diagnostics), with a lower limit of detection of 15 IU/ml, have been introduced. Sarrazin et al. [2010] compared virological response rates that were originally tested by COBAS Amplicor assay with those retested by COBAS TaqMan assay, using the same cohort. Among genotype 1 patients, complete early virological response and sustained virological response rates were similar when virological responses were defined as <50 IU/ml by Amplicor assay (77% and 87%) and <15 IU/ml by TaqMan assay (76% and 88%). Therefore, measuring HCV RNA by the Amplicor assay in this study would have little affects on the results.

In conclusion, the results have demonstrated that substitution of core aa 70 could be independently associated with an insufficient decline in HCV RNA level during first 12 weeks, and substitution of core aa 91 was independently associated with detectable HCV RNA at week 24, all of which were considered to be important negative predictors of attaining sustained virological response in patients with HCV genotype 1 treated with Peg-IFN plus ribavirin. On the other hand, only dose exposure of ribavirin and no complete early virological response was independent predictors of virological relapse among patients with end-of-treatment response, not substitution of core aa 70 or 91. The aa substitution patterns of the HCV core protein can be an important pretreatment predictor for non-response in patients with HCV genotype 1 treated with Peg-IFN plus ribavirin, but not for relapse after the completion of therapy.

Hepatocellular carcinomas can develop in simple fatty livers in the setting of oxidative stress

Sir,

It is doubtless that non-alcoholic fatty liver disease (NAFLD) has become a critical public health issue in most developed countries.[1] In addition to its close association with metabolic disorders and cardiovascular events, NAFLD itself can progress to life-threatening liver diseases, cirrhosis and hepatocellular carcinoma (HCC).[1,2] Surprisingly, recent clinical observations have revealed that HCC can develop in non-cirrhotic, but steatotic livers without significant fibrosis.[3,4] In the reports, authors emphasised the importance of underlying metabolic disorders and oxidative stress in hepatocarcinogenesis in such NAFLD cases.

We herein report a case of NAFLD complicated by HCC, in which the potential contribution of oxidative stress to hepatocarcinogenesis in NAFLD has been further strongly suggested.

In May 2006, a 72-year-old obese Japanese man was admitted to the National Hospital Organization Osaka National Hospital, Japan, because of a hepatic nodule. The patient had a 5 year medical history of hypertension and fatty liver. He underwent an operation for abdominal aortic aneurysm in April 2004, and had since been an outpatient. Follow-up abdominal ultrasonography showed, in addition to hepatic steatosis, a nodular lesion approximately 2 cm in diameter in the left lobe of the liver. The hepatic nodule had been growing larger, and findings of computed tomography (CT) strongly suggested that it was HCC (Fig. 1).

On admission, he appeared to be healthy except for obesity, and the laboratory test results showed normal serum levels of transaminases and negativity for hepatitis B and C viruses. After the examinations, under the tentative diagnosis of HCC, a surgical operation was performed to remove the left lobe of the liver. The cut surface of the liver sample was smooth and yellowish-brown, and demonstrated the clearly circumscribed nodule 5 cm in diameter (Fig. 2). Histological examination revealed that the nodular lesion was well-differentiated HCC (Fig. 3A), and the background hepatic disorder was simple steatosis without inflammation and fibrosis (Fig. 3B). Routine pathological examination couldn't detect any causative factors in hepatocarcinogenesis, such as iron overload. However, an immunohistochemical analysis revealed that as well as tumour cells, a few non-tumourous hepatocytes showed immunoreactivity for anti-oxidised phosphatidylcholine (oxPC; Fig. 3A,B insets), a marker of

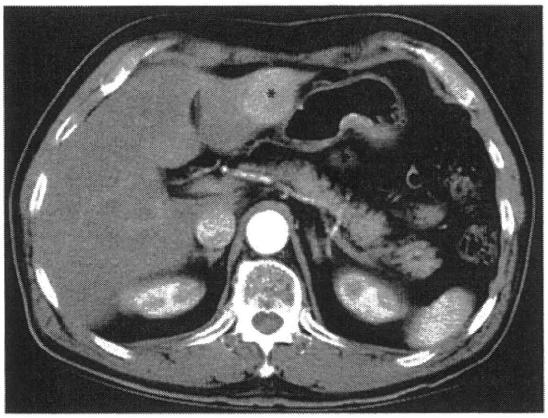

Fig. 1 Findings of computed tomography. A hypervascular nodule is seen in the left lobe of the liver (asterisk).

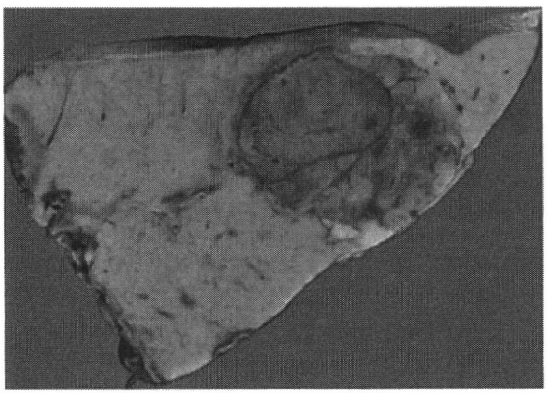

Fig. 2 The cut-surface of the liver sample. A well-circumscribed nodular lesion 5 cm in diameter is present.

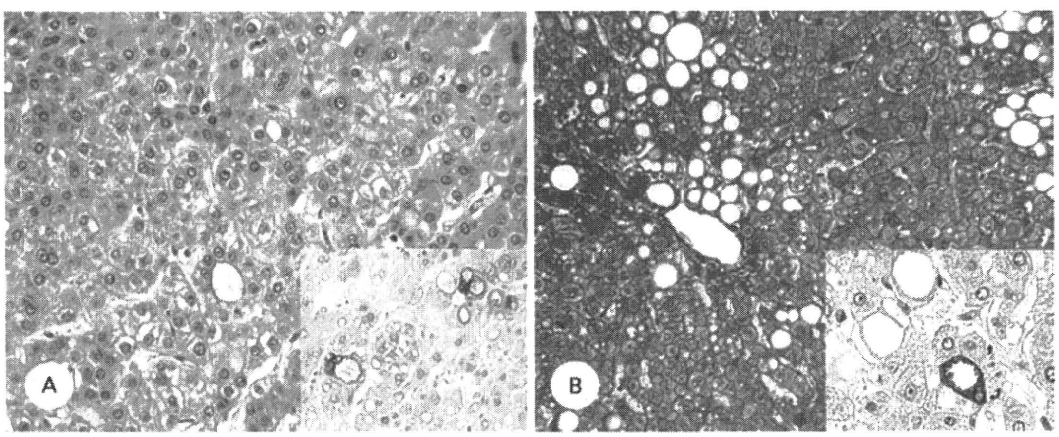

Fig. 3 Microscopic findings of the liver sample. (A) The hepatic nodule consists of well-differentiated HCC (H&E). (B) A background liver condition is simple steatosis without fibrosis (Azan-Mallory stain for collagen). Insets: steatotic liver cells of both tumourous and non-tumourous portions are positive for oxPC (immunoperoxidase with anti-oxPC).

oxidative cellular injury.[5] The immunoreactivity was found restrictively in steatotic cells in both tumourous and non-tumourous portions. It suggested that the steatosis-related oxidative hepatocellular injury had persisted and had played a certain role in the development of HCC. His postoperative course was uneventful and he was discharged. Follow-up examinations have been done every 3 months, resulting in no evidence of tumour recurrence. When last seen, in December 2009, he was well.

Like the present case, HCC can develop in non-inflammatory, non-fibrotic, but steatotic livers. A previous case report of HCC arising in the absence of advanced NAFLD emphasised the potential roles for metabolic factors (diabetes, hypertension, obesity and dyslipidaemia) and oxidative stress in hepatocarcinogenesis.[4] Oxidative stress is generally recognised as an important factor in hepatocarcinogenesis.[2,6] Our immunohistochemical results showed oxPC-positive steatotic hepatocytes in the background liver tissue of HCC. OxPC, one of the lipid peroxides, is a highly specific marker of oxidative damage. In our previous observation, its immunoreactivity was seen mainly in steatotic or degenerated hepatocytes in NAFLD, and only in some Kupffer cells in normal liver tissues.[5] Hence, the present result suggested that the fatty liver had chronically been exposed to oxidative stress, which was probably initiated prior to hepatocarcinogenesis. To our knowledge, this is the first direct evidence of oxidative hepatocellular injury occurring in simple fatty livers complicated by HCC. Excess fat accumulation itself, even in the absence of inflammation, can be a source of oxidative stress that induces hepatocarcinogenesis. In conclusion, simple steatosis-related oxidative stress should be considered as one of the risk factors of HCC.

Benign prostatic glands as a tissue component of testicular teratoma: an uncommon histological finding

Sir,

The occurrence of benign prostatic tissue as a component of testicular teratoma has only been described as a single case report.[1] This may be due to its rare occurrence, as well as the failure of the diagnostic pathologist to recognise glands as prostatic on routine sections and to subsequently confirm this by immunohistochemistry. In our laboratory we utilise Solufix (Tissugen, Australia), a glutaraldehyde-based tissue fixative for routine histology. This agent preserves the spermine content of prostatic secretory granules (PSG) which stain intensely with eosin on routine stains allowing easy recognition of prostatic epithelium.[2]

We present two cases of benign prostatic glandular tissue occurring in two patients with primary testicular tumours; a mature teratoma in a 35-year-old male and a mixed germ cell tumour (30% mature teratoma) in a 39-year-old male. Each patient underwent routine inguinal orchidectomy for a clinically detected testicular mass.

On microscopy, benign gland structures were recognised which were lined by two cell types and bore some resemblance to prostatic acini. These glands were highlighted by their intense eosinophilic PSG (Fig. 1 and 2), and were distributed either singularly or as clusters separated by bland stroma. Lining epithelium showed variable morphology ranging from bland epithelial cells consistent with benign prostatic glands (Fig. 1) to epithelial cells with larger nuclei and prominent nucleoli (Fig. 2), consistent with prostatic intraepithelial neoplasia (PIN). The prostatic nature of the glands was subsequently confirmed by strong diffuse cytoplasmic reactivity with immunohistochemistry for PSA (Dako, USA; Fig. 1 inset) and prostatic acid phosphatase (Dako; not shown). Basal cells were confirmed with immunostaining for high molecular weight cytokeratin 34βE12 (Dako; Fig. 2 inset).

Recognition of the first case prompted a histological review of all testicular teratomas over a 10 year period which included 20 testicular tumours comprising pure teratomas ($n = 10$) and mixed germ cell tumours with a mature teratoma component of >10% ($n = 10$). This review identified the second case,

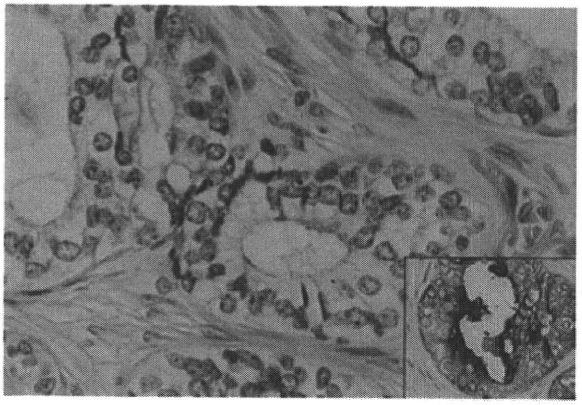

Fig. 1 Benign prostatic glands within a testicular germ cell tumour surrounded by bland stroma. Small eosinophilic granules (prostate secretory granules) are seen in the apical cytoplasm confirming prostatic epithelial differentiation. Inset: These cells are strongly labelled with PSA immunostaining.

Background & Aims: This study investigated the efficacy and adverse effects of pegylated interferon (Peg-IFN) plus ribavirin therapy in aged patients with chronic hepatitis C (CH-C).

Methods: A total of 1040 naïve patients with CH-C (genotype 1, $n = 759$; genotype 2, $n = 281$), of whom 240 (23%) over 65 years old (y.o.), were treated with Peg-IFN alfa-2b plus ribavirin and assessed after being classified into five categories, according to age.

Results: The discontinuance rate was higher for patients over 70 y.o. (36%), the most common reason being anemia. In the presence of genotype 1, the SVR rate was similar (42–46%) among patients under 65 y.o. and declined (26–29%) among patients over 65 y.o. For patients over 65 y.o., being male (Odds ratio, OR, 3.5, $p = 0.035$) and EVR (OR, 83.3, $p < 0.001$) were significant factors for SVR, in multivariate analysis. The Peg-IFN dose was related to EVR, and when EVR was attained, 76–86% of patients over 65 y.o. achieved SVR. SVR was not achieved (0/35, 0/38, respectively) if a 1-log decrease and a 2-log decrease were not attained at week 4 and week 8, respectively. In the presence of genotype 2, the SVR rate was similar (70–71%) among patients under 70 y.o. and declined among patients over 70 y.o. (43%).

Conclusions: Aged patients up to 65 y.o. with genotype 1 and 70 y.o. with genotype 2 can be candidates for Peg-IFN plus ribavirin therapy. The response-guided therapy can be applied for aged patients with genotype 1.

Introduction

Pegylated interferon (Peg-IFN) plus ribavirin combination therapy has led to a marked progress in the treatment of chronic hepatitis C (CH-C) [1–4]. However, in aged patients, problems remain with respect to its anti-viral effect and tolerability [5–9]. Recently, the addition of a protease inhibitor to Peg-IFN plus ribavirin combination therapy has been reported, on the one hand, to improve the anti-viral effect, and, on the other hand, to increase side effects, especially severe anemia [10–11].

Therefore, this new therapy does not solve the problems encountered when treating aged patients.

With aging, the progression of liver fibrosis and the occurrence of hepatocellular carcinoma (HCC) have been shown to be accelerated, especially in patients over 60 y.o. [12–14]. In general, the anti-viral therapy can lead to an improvement in liver fibrosis and thus diminish the risk of HCC and ameliorate the prognosis in patients with CH-C [15–21]. Among aged patients, those results are mainly achievable upon eradication of the hepatitis C virus (HCV) [18,21]. Accordingly, the first goal of treatment of aged patients with a high-risk of HCC should be HCV elimination.

Thus, a treatment strategy, aiming at the improvement of the anti-viral efficacy in aged patients, should be established based on detailed large-scale studies.

Some points need to be further elucidated when using the Peg-IFN plus ribavirin combination therapy for the treatment of aged patients with CH-C: (i) the characteristics before treatment

Please cite this article in press as: Oze T et al. Indications and limitations for aged patients with chronic hepatitis C in pegylated interferon alfa-2b plus ribavirin combination therapy. J Hepatol (2011), doi:10.1016/j.jhep.2010.07.043

Research Article

that would lead to the successful elimination of HCV, (ii) the prediction factors of treatment efficacy after the initiation of the therapy, and (iii) the utility of a response-guided therapy established in the treatment.

In the present study, using a large cohort, we aimed at clarifying these points taking into account the patients' age.

Patients and methods

Patients

This study was a retrospective, multicenter trial conducted by the Osaka University Hospital and other institutions participating in the Osaka Liver Forum. A total of 1040 naïve patients with CH-C were enrolled between December 2004 and June 2007. All patients were Japanese, infected with a viral load of more than 10^5 IU/ml, and treated with a combination of Peg-IFN alfa-2b plus ribavirin. Patients were excluded from the study if they had decompensated cirrhosis or other forms of liver disease (alcohol liver disease, autoimmune hepatitis), co-infection with hepatitis B or anti-human immunodeficiency virus. This study was conducted according to the ethical guidelines of the 1975 Declaration of Helsinki and informed consent was obtained from each patient.

Treatment

All patients received Peg-IFN alfa-2b (PEGINTRON; Schering-Plough, Kenilworth, NJ, USA) plus ribavirin (REBETOL; Schering-Plough). Treatment duration was 48 weeks for patients with genotype 1 and 24 weeks for those with genotype 2. As a starting dose, Peg-IFN alfa-2b was given once weekly, at a dosage of 1.5 μg/kg, and ribavirin was given at a total dose of 600–1000 mg/day based on body weight (body weight <60 kg, 600 mg; 60–80 kg, 800 mg; >80 kg, 1000 mg), according to a standard treatment protocol for Japanese patients.

Dose reduction and discontinuance

Dose modification followed, as a rule, the manufacturer's drug information on the intensity of the hematologic adverse effects. The Peg-IFN alfa-2b dose was reduced to 50% of the assigned dose when the white blood cell (WBC) count was below 1500/mm^3, the neutrophil count below 750/mm^3 or the platelet (Plt) count below 8×10^4/mm^3, and was discontinued when the WBC count was below 1000/mm^3, the neutrophil count below 500/mm^3 or the Plt count below 5×10^4/mm^3. Ribavirin was also reduced from 1000 to 600 mg, 800 to 600 mg, or 600 to 400 mg when the hemoglobin (Hb) was below 10 g/dl, and was discontinued when the Hb was below 8.5 g/dl. Peg-IFN alfa-2b and ribavirin had to be both discontinued if there was a need to discontinue either of them. No ferric medicine or hematopoietic growth factors, such as epoetin alpha, or granulocyte–macrophage colony stimulating factor (G-CSF), were administered.

Virologic assessment and definition of virologic response

Serum HCV RNA level was quantified using the COBAS AMPLICOR HCV MONITOR test, version 2.0 (detection range 6–5000 KIU/ml; Roche Diagnostics, Branchburg, NJ) and qualitatively analyzed using the COBAS AMPLICOR HCV test, version 2.0 (lower limit of detection 50 IU/ml; Roche Diagnostics). The rapid virologic response (RVR) was defined as undetectable serum HCV RNA at week 4; the early virologic response (EVR) as undetectable serum HCV RNA at week 12; and the late virologic response (LVR) as detectable serum HCV RNA at week 12 and undetectable serum HCV RNA at week 24. Moreover, the sustained virologic response (SVR) was defined as undetectable serum HCV RNA, 24 weeks after treatment.

According to the protocol, genotype 1 patients, with less than a 2-log decrease in HCV RNA level at week 12 compared to the baseline, or with detectable serum HCV RNA at week 24, had to stop the treatment and were regarded as non-response (NR). Treatment discontinuance was evaluated except for those patients who had discontinued the treatment at up to 24 weeks, due to absence of response. Anti-viral efficacy was evaluated, for all study patients, using the intention-to-treat analysis (ITT analysis) and the per protocol analysis (PP analysis) for patients without treatment discontinuation due to side effects, and was assessed considering the definition of EVR or LVR for genotype 1, and RVR or non-RVR for genotype 2, as previously reported [1].

Assessment of drug exposure

The amounts of Peg-IFN alfa-2b and ribavirin, taken by each patient during the full treatment period, were evaluated by reviewing the medical records. The mean doses of Peg-IFN alfa-2b and ribavirin were calculated individually as averages, on the basis of the body weight at baseline: Peg-IFN alfa-2b expressed as μg/kg/week, ribavirin expressed as mg/kg/day.

Statistical analysis

Patients' baseline data are expressed as means ± SD or median values. To analyze the difference between baseline data, ANOVA or Mantel–Haenszel Chi-square test were performed. Factors associated with the viral response were assessed by univariate analysis using the Mann–Whitney *U* test or Chi-square test and multivariate analysis using logistic regression analysis. A two-tailed p value <0.05 was considered significant. The analysis was conducted with SPSS version 15.0J (SPSS Inc., Chicago, IL).

Results

Patient's profile

Baseline characteristics of the patients categorized by age are shown in Table 1.

Genotype 1 patients (n = 759) were distributed into five categories: 266 patients were under 55 y.o. (group 1A), 159 were 55–59 y.o. (group 1B), 149 were 60–64 y.o. (group 1C), 134 were 65–69 y.o. (group 1D), and 51 were 70 y.o. or older (group 1E). With advancing age, the male-to-female ratio and peripheral blood cell count (WBC, neutrophil count, Red blood cell (RBC), Hb, Plt) decreased significantly. Patients with a progression of liver fibrosis (METAVIR fibrosis score 3 or 4) significantly increased with age (Table 1A).

Genotype 2 patients (n = 281) were also distributed into five categories: 145 patients were under 55 y.o. (group 2A), 43 were 55–59 y.o. (group 2B), 38 were 60–64 y.o. (group 2C), 41 were 65–69 y.o. (group 2D), and 14 were 70 y.o. or older (group 2E). As observed in genotype 1 patients, the peripheral blood cell count decreased and the ratio of advanced fibrosis (score 3–4) increased significantly with age (Table 1B). For both genotypes, the initial doses of Peg-IFN in patients over 70 y.o. were lower than in those under 70 y.o., this was not the case for the ribavirin doses.

Dose reduction and discontinuance for adverse event

The overall discontinuance rate of treatment was 15% (140/919); 18% (112/639) for genotype 1 and 10% (28/280) for genotype 2, respectively. Table 2 shows the reason for and the rate of treatment discontinuance according to age. The discontinuance rate increased with age, being 10% (36/363) for patients under 55 y.o., 15% (27/182) for patients with 55–59 y.o., 17% (28/169) for patients with 60–64 y.o., 19% (28/147) for patients with 65–70 y.o., and significantly higher, 36%, (21/58) for patients over 70 y.o. The discontinuance of treatment due to hemolytic anemia was significantly higher for patients over 70 y.o. as compared to those under 70 y.o. (<70 y.o., 1% (9/861) vs. ⩾70 y.o., 16% (9/58), p <0.0001).

The rate without dose reduction of both drugs decreased with age (<55 y.o., 41% (171/411); 55–59 y.o., 20% (40/202); 60–64 y.o., 26% (48/187); 65–69 y.o., 23% (41/175); ⩾70 y.o., 18% (12/65)). In the presence of genotype 1, the mean dose of Peg-IFN

during the whole treatment period was lower (1.1 ± 0.3 μg/kg/week) for patients over 70 y.o. than for those under 70 y.o. (1.3 ± 0.3 μg/kg/week) and that of ribavirin decreased with age (<55 y.o., 10.3 ± 1.9 mg/kg/day; 55–59 y.o., 9.8 ± 1.9 mg/kg/day; 60–64 y.o., 9.3 ± 2.3 mg/kg/day; 65–69 y.o., 9.2 ± 2.3 mg/kg/day; ⩾70 y.o., 8.5 ± 2.5 mg/kg/day). The same tendency was observed with genotype 2.

Sustained virologic response

In genotype 1 patients, the overall SVR rate was 40% (305/759), being 46% (123/266) for group 1A, 44% (70/159) for group 1B, 42% (62/149) for group 1C, 26% (35/134) for group 1D, and 29% (15/51) for group 1E, following ITT analysis. The same tendency was observed using the PP analysis ($n = 647$). The SVR rates for patients over 65 y.o. were significantly lower than those for patients under 65 y.o. (ITT analysis: ⩾65 y.o., 27% vs. <65 y.o., 44%, $p < 0.0001$; PP analysis: ⩾65 y.o., 31% vs. <65 y.o., 50%, $p < 0.0001$) (Fig. 1A). Among genotype 1 patients over 65 y.o., the SVR rate was significantly lower for female patients than for male patients (ITT analysis: male, 40% (31/77) vs. female, 18% (19/108), $p < 0.001$; PP analysis: male, 49% (27/55) vs. female, 20% (18/90), $p < 0.001$).

Moreover, for genotype 2 patients, the overall SVR rate was 78% (220/281), being 88% (128/145) for group 2A, 70% (30/43) for group 2B, 71% (27/38) for group 2C, 71% (29/41) for group 2D, and 43% (6/14) for group 2E, following ITT analysis. The same tendency was observed with the PP analysis ($n = 253$). The SVR rates for patients over 70 y.o. were significantly lower than those for patients under 70 y.o. (ITT analysis: ⩾70 y.o., 43% vs. <70 y.o., 80%, $p < 0.0001$; PP analysis: ⩾70 y.o., 56% vs. <70 y.o., 85%, $p < 0.05$) (Fig. 1B). Among patients over 70 y.o. with genotype 2, the difference according to gender was not clear because of the small sample.

Table 4. Multivariate analysis for the factors associated with SVR among all patients.

Factor	Category	Odds ratio	95% CI	p
Age (y.o.)	<65 / ≥65	0.485	0.295 - 0.799	0.005
Sex	male / female	0.524	0.353 - 0.777	0.001
Platelets ($\times 10^4/mm^3$)	<12 / ≥12	1.780	1.039 - 3.049	0.040
Serum HCV RNA (KIU/ml)	<2000 / ≥2000	0.599	0.401 - 0.896	0.010
Histology (METAVIR): Fibrosis	0 - 2 / 3 - 4	0.599	0.333 - 1.076	0.090

y.o. and 86% of patients over 70 y.o. achieved SVR, and these SVR rates compared favorably with those of younger patients. On the other hand, the SVR rates for patients with LVR ranged from 17% to 46%, which were lower than those for EVR patients in each age group, and no significant differences of SVR rates were found among LVR patients by age.

With genotype 2, patients with RVR achieved high SVR rates ranging from 82% to 100% regardless of age. Even for patients without RVR, 96% of those under 55 y.o. attained SVR, a rate that was significantly higher than that for patients over 55 y.o. (50%, 14/28) (p <0.001).

Factors associated with SVR for genotype 1

The factors associated with SVR were assessed for the variables shown in Table 1. The factors selected as significant by the univariate analysis: age, gender, WBC, neutrophils, RBC, Hb, Plt, aspartate aminotransferase, serum HCV RNA level, the degree of liver fibrosis, and the initial dose of Peg-IFN, were evaluated by multivariate logistic regression analysis. The factor of age over 65 y.o. was the independent factor for SVR (p = 0.005), apart from the gender (p = 0.001), Plt value (p <0.05), and serum HCV RNA level (p = 0.01) (Table 4).

Factors associated with EVR and SVR for patients over 65 y.o. with genotype 1

The results of univariate analysis for EVR among patients over 65 y.o. are shown in Table 5A. Gender, Plt value, and mean dose of Peg-IFN during the first 12 weeks were factors significantly associated with EVR. In multivariate analysis, the mean dose of Peg-IFN during the first 12 weeks was the independent factor for EVR (p = 0.03), apart from gender (p = 0.002) (Table 5B). The EVR rates were 41% (41/101) in patients who received ≥1.2 μg/kg/week on average during the first 12 weeks, and declined to 36% (8/22) in patients given 0.9–1.2 μg/kg/week of Peg-IFN, and to 14% (3/22) in patients administered with <0.9 μg/kg/week of Peg-IFN.

The baseline and on-treatment factors, which are correlated with the SVR among the patients over 65 y.o., were assessed by univariate and multivariate analyses. Univariate analysis showed that factors significantly associated with SVR were gender and virologic response (Table 6A), and they were also selected as significant independent factors in multivariate analysis (p = 0.035, p <0.001) (Table 6B).

Negative prediction of SVR for patients over 65 y.o. with genotype 1

We tried positive and negative predictions of SVR for aged patients, focusing on the decrease of HCV RNA at treatment week 4 and 8. The SVR rate was 47% (29/62) for patients with more than a 1-log decrease in HCV RNA level at week 4, while no patients with less than a 1-log decrease at week 4 attained SVR (0/35) (p <0.0001). Similarly, 55% (35/64) of patients with more than a 2-log decrease at week 8 attained SVR, whereas no patients with less than a 2-log decrease at week 8 attained SVR (0/38) (p <0.0001).

Discussion

Peg-IFN plus ribavirin combination therapy can improve anti-viral efficacy and is presently recommended as first-line therapy [1–4]. However, with respect to aged patients with CH-C, there have been only a few small-scale cohort studies which reported poor anti-viral effect and poor tolerability in comparison with non-aged patients [5–9]. The problem in the treatment of aged patients with CH-C is most serious in Japan, because HCV carriers in Japan are 10–20 years older than those in the United States and European countries [22]. Therefore, in the present study, we examined the efficacy and prevalence of side effects with a focus on patient's age using a large-scale cohort.

With respect to the side effects and discontinuance rate of treatment in aged patients with CH-C, treated with Peg-IFN plus ribavirin combination therapy, Reddy et al. reported that there was no difference related to the incidence and reason for side effects between non-aged and aged patients [6]. Another paper reported that the incidence of side effects was more frequent in aged patients [5]. In our study, not only the continuance rate without reduction of both drug decreased with age, but also the discontinuance rate of treatment increased with age, with a third of the patients over 70 y.o. discontinuing the treatment. The discrepancy, existing between our results and those reported in the former study cited above, is due to the difference in the number of aged patients enrolled; Reddy' s study analyzed a small cohort including only a few cases of patients over 65 y.o. and classified all those over 50 y.o. as aged patients.

Discontinuance of treatment due to progression of anemia was significantly higher in patients over 70 y.o., accounting for 43% (9/21) of the discontinuance in this group. Although the ratio of advanced fibrosis (score 3–4) increased with age, the high discontinuance rate due to anemia among patients over 70 y.o. was similar regardless of the progression of fibrosis (F0-2: <70 y.o., 1% (6/559) vs. ⩾70 y.o., 21% (6/28), p <0.0001; F3-4: <70 y.o., 0% (0/83) vs. ⩾70 y.o., 22% (2/9), p <0.0001). It is possible that poor hematopoietic function and renal function led to the progression of anemia in aged patients. For patients who develop severe anemia, using epoetin alpha or taribavirin, which are ribavirin prodrugs, has been shown to result in a lower incidence of anemia, although no significant increase of SVR has been reported so far, even with the addition of taribavirin to Peg-IFN [23–24].

With genotype 1 patients, the SVR rates were almost equal up to 65 y.o. (49–50%), but decreased to 31% (45/145) among the patients that were over 65 y.o., and even for those who completed the entire treatment schedule in this study. Since the degree of liver fibrosis and drug exposure have been shown to be associated with anti-viral efficacy, the progression of liver fibrosis or decrease of drug exposure with age could account for the reduction of SVR rate among the aged patients. However, the stratified analysis, according to the progression of liver fibrosis and drug exposure, revealed that older patients still yielded low a SVR rate (F0-2, Peg-IFN during the first 12 weeks ⩾1.2 μg/kg/week:<65 y.o., 55% (143/261) vs. ⩾65 y.o., 33% (15/46), p <0.0001; F0-2, Peg-IFN during the first 12 weeks <1.2 μg/kg/week:<65 y.o., 43% (26/60) vs. ⩾65 y.o., 23% (6/26), p = 0.07), which means that older patients would be difficult to treat. From our results showing a low SVR rate and a high discontinuance rate for patients over 65 y.o., the genotype 1 patients under 65 y.o were those who benefited the most from Peg-IFN plus ribavirin combination therapy. The high prevalence of treatment failure (non-SVR) among the aged patients seems to be due to the high populations of NR and LVR (Fig. 2). A high population of LVR is considered to lead to a higher transient response rate among aged patients, since those over 65 y.o. with LVR showed a much higher relapse rate (79%, 15/19) than those with EVR (21%, 11/52) (p <0.0001), as can be seen from Table 3.

In this study, multivariate analysis for SVR, in patients over 65 y.o., showed that the factors associated with SVR were EVR and gender. This indicates that better SVR can be expected even with older patients if EVR is attained and response-guided therapy guidelines can be useful for aged patients. A low SVR rate among aged female patients was as previously reported [7], although the mechanism remains unclear. This finding suggests that female patients should be treated before 65 y.o.

The next question is how aged patients should be treated in order to attain EVR. We have examined the impact of drug exposure on treatment efficacy [25–26] and reported that Peg-IFN is dose-dependently correlated with EVR [25]. In this study, the dose-dependent efficacy of Peg-IFN for EVR was also revealed in aged patients over 65 y.o., with less than 0.9 μg/kg/week of Peg-IFN leading to a low EVR rate for aged patients. If patients are difficult to treat with more than 1.2 μg/kg/week of Peg-IFN, using as much Peg-IFN as possible is desirable, in order to attain higher EVR rates. Accordingly, a reduction of Peg-IFN to 80% may need to be considered, although the manufacturer's drug information recommends reducing the dose of Peg-IFN to 50% of the assigned one. Since reduction of Peg-IFN has been reported to not affect the SVR rate after HCV RNA disappearance [26], using G-CSF for aged patients who develop severe neutropenia can be beneficial, especially in the first 12 weeks.

We also examined the negative prediction of SVR, i.e. an HCV RNA decrease at an earlier point of treatment than the usual prediction at treatment week 12 of a 2-log decrease, among aged patients with CH-C treated by Peg-IFN plus ribavirin combination therapy. We found that none of the patients without a 1-log decrease at week 4 or a 2-log decrease at week 8 could attain SVR, even if the complete treatment duration was given, the negative predictive value (NPV) for SVR equaled 100%. This earlier prediction is applied just as well to aged patients as to non-aged patients in order to avoid additional adverse effects. Recently, a genetic polymorphism near the *IL28B* gene has been reported to be associated with non-response to Peg-IFN plus ribavirin combination therapy [27–29], which is beneficial to patients. Nevertheless, even in the presence of this genetic polymorphism, NPV for SVR remains at 57–87%; 100% accuracy is not guaranteed. Thus, in addition to the pretreatment prediction, an earlier negative prediction for SVR during treatment is also considered to be useful.

We have shown in this study that, in the presence of genotype 2, HCV was easily eliminated even among aged patients; the SVR rates were over 75% for patients who had completed the treatment, and these rates were similar up to 70 y.o. The SVR rate of genotype 2 patients over 70 y.o. was 43%, however, the age limitation of the treatment among patients over 70 y.o. remains unclear, because of the small number of patients enrolled in this study. We have reported that the reduction of treatment drugs had little effect on anti-viral efficacy for patients with genotype 2, meaning that SVR can be attained even with aged patients who are usually given lower drug doses than non-aged patients [30]. Patients under 70 y.o. with genotype 2 should, at least, benefit from this therapy. The SVR rate was maintained among genotype 2 patients being 65–69 y.o., compared to genotype 1 patients. The higher efficacy with shorter treatment duration in genotype 2 aged patients can account for it.

In conclusion, the strategy of a response-guided therapy and an earlier negative prediction for SVR may be beneficial for aged patients, especially those with genotype 1. At present, aged patients up to 65–70 y.o. with CH-C can be candidates for Peg-IFN plus ribavirin combination therapy, if its efficacy and adverse effects are fully taken into account. At the same time, there is an urgent need to establish new treatment procedures, such as combination therapy with protease inhibitor plus polymerase inhibitor without Peg-IFN or ribavirin, for non-responders or patients

Key Words
Adjuvant chemotherapy · S-1 · Recurrent gastric cancer · Overall survival · Efficacy of chemotherapy

Abstract
Background: As S-1 monotherapy has recently become the standard adjuvant regimen for stage II-III gastric cancer patients after curative gastrectomy in Japan, the question whether adjuvant S-1 affects the subsequent clinical course of relapsed patients has attracted great concern. ***Patients and Methods:*** We retrospectively evaluated the effect of adjuvant S-1 on survival following recurrence and efficacy of first-line treatment in patients with recurrent gastric cancer after curative gastrectomy. A total of 89 patients were evaluated. Thirty patients received adjuvant S-1 (cohort A), 10 patients were given adjuvant chemotherapy with other oral 5-FU agents (cohort B) and 49 patients received no adjuvant chemotherapy (cohort C). ***Results:*** Median survival time following recurrence was 287 days in cohort A, 451 days in B and 547 days in C, with a significant difference between A and C ($p = 0.0034$). Response rates of the first-line chemotherapy after recurrence were 6.7, 30.0 and 42.9% in cohorts A, B and C, respectively, with a significant difference between A and C ($p = 0.0007$). On multivariate analysis, S-1 adjuvant chemotherapy was independently associated with poor prognosis after recurrence (hazard ratio 2.64). ***Conclusion:*** S-1 adjuvant chemotherapy significantly reduced survival and response to first-line chemotherapy following recurrence in patients with recurrent gastric cancer.

Introduction

Although several meta-analyses have suggested a survival benefit provided by adjuvant chemotherapy for gastric cancer [1–6], there have been only a few treatments with their efficacy established in large clinical trials. Postoperative radiotherapy with 5-FU plus leucovorin has become a standard adjuvant therapy in the US [7], while peri-operative triplet regimen with epirubicin, cisplatin and 5-FU is standard in the UK [8]. Recently in Japan, the ACTS-GC trial has verified the efficacy of S-1 adjuvant chemotherapy after curative gastrectomy for stage II-III disease [9]. However, around 30% of patients still develop recurrence afterwards despite adjuvant S-1. As the number of patients relapsing after S-1 adjuvant chemotherapy increases, it becomes of great concern whether adjuvant S-1 affects the subsequent clinical behavior of the recurrent disease.

This retrospective study was conducted to evaluate the effect of S-1 adjuvant chemotherapy, in comparison with other 5-FU agents or no adjuvant chemotherapy, on sur-

vival following recurrence and efficacy of first-line chemotherapy given at the time of relapse in patients with recurrent gastric cancer after curative gastrectomy.

Patients and Methods

Patients

A total of 95 patients with recurrent gastric cancer after curative gastrectomy were found at our institution between April 1999 and October 2008. Among them, 89 patients enrolled in this retrospective study fulfilled the following criteria: (1) histologically proven recurrent gastric adenocarcinoma; (2) stage II, III or IV primary disease without any distant metastasis in accordance with the guidelines of the Japanese Gastric Cancer Association [10]; (3) either adjuvant chemotherapy with S-1 or other oral 5-FU agents (UFT or 5′-FUDR) lasting more than 4 weeks or no adjuvant treatment; (4) performance status of 2 or less on the Eastern Cooperative Oncology Group scale; (5) adequate bone marrow function (white blood cell count 4,000–12,000/mm^3, platelet count ≥100,000/mm^3 and hemoglobin ≥8.0 g/dl), hepatic function (total bilirubin ≤1.5 mg/dl, serum transaminases ≤100 μ/l) and renal function (serum creatinine ≤ the upper institutional limit); (6) no other severe medical conditions; (7) no other concurrent active malignancy.

Overall Survival, Efficacy of First-Line Chemotherapy and Statistics

Overall survival (OS) after recurrence was defined as the time from the date of recurrence to the date of death from any cause or the last follow-up. OS was calculated using the Kaplan-Meier method and compared with the log-rank test. Univariate and multivariate analyses were performed by the Cox proportional hazards model to identify variables independently associated with poor prognosis after recurrence.

During the first-line chemotherapy after recurrence, each patient with a measurable lesion was assessed for an objective response to treatment according to the Response Evaluation Criteria in Solid Tumors [11] with computed tomography scans performed every 2 to 3 months until disease progression. Disease control rate (DCR) represented the percentage of patients with complete response, partial response or stable disease (SD). Patients only with nonmeasurable lesions were evaluated as stable disease if neither complete disappearance (complete response) nor obvious progression of the recurrent disease were observed on computed tomography scans.

Differences in proportion were evaluated with the χ^2 test and the differential significance of age was estimated by the Kruskal-Wallis test. Statistical results were considered to be significant with a p value of less than 0.05.

Results

Patient Characteristics

Eighty-nine patients were categorized into the 3 cohorts shown in table 1. Thirty patients in cohort A, 18 males and 12 females with a median age of 62.5 years (range: 32–83), received S-1 adjuvant chemotherapy. S-1 was given orally using a standard dose and schedule (80 mg/m^2/day, for 28 consecutive days followed by a 14-day rest, repeated for 1 year) [9]. Nine patients completed the planned 1-year administration of adjuvant S-1, while 11 patients discontinued the treatment within the first 6 months and 10 patients in the second 6 months after the initiation of S-1 adjuvant chemotherapy. The reasons for treatment withdrawal were treatment toxicity in 1, and recurrent disease in 20 patients. The median duration of adjuvant S-1 administration was 211 days. In cohort B, 10 patients, 6 males and 4 females with a median age of 63.0 years (range: 35–78), were given adjuvant chemotherapy with oral 5-FU agents other than S-1. UFT (a combination of uracil and tegafur at a molar ratio of 4:1) was administered at a dose of 400 mg/body/day in 6 patients and 5′-DFUR (5′-deoxy-5-fluorouridine) at a dose of 800 mg/body/day in 4 patients. Two patients completed the planned 1-year administration of adjuvant UFT/5′-DFUR, while 3 patients discontinued the treatment within the first 6 months and 5 patients in the second 6 months after the initiation of adjuvant chemotherapy. The rea-

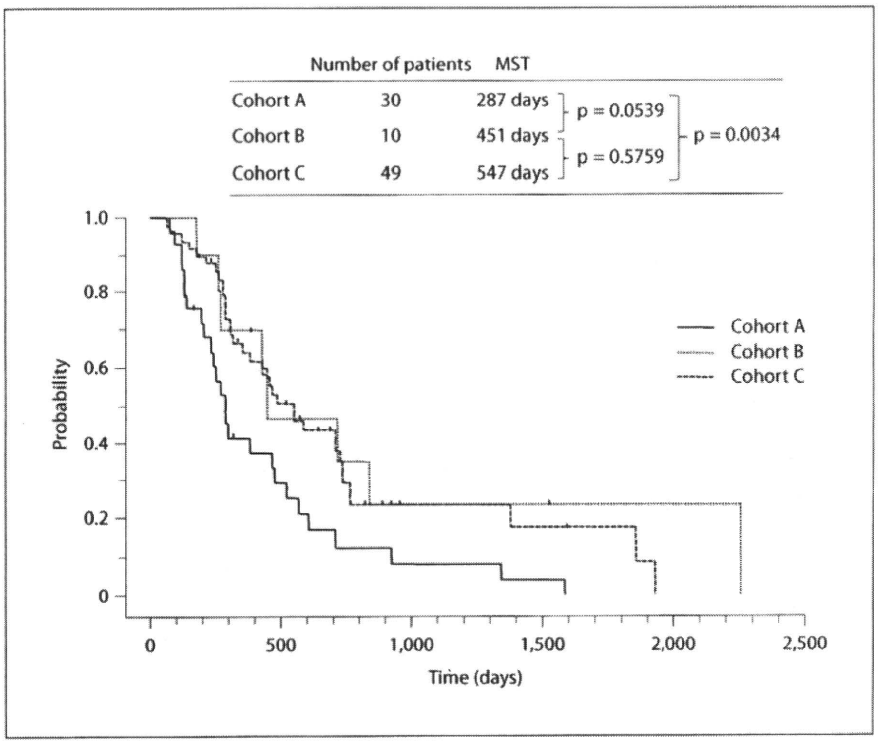

Fig. 1. OS after recurrence.

sons for treatment withdrawal were patient refusal in 1 and recurrent disease in 7 patients. The median duration of adjuvant 5-FU agent administration was 180 days. Forty-nine patients in cohort C, 35 males and 14 females with a median age of 59.0 years (range: 42–84), received no adjuvant chemotherapy. Histologically, around one third of patients had intestinal-type adenocarcinoma and two thirds had diffuse-type adenocarcinoma in each cohort. As for the initial stage of the primary tumor after curative gastrectomy, stage IV disease was significantly more frequent in cohort A than in the other cohorts ($p = 0.0053$). A measurable recurrent lesion was seen in 50–60% of each cohort and multiple metastatic sites were present in 10% of all patients. The disease-free interval (DFI), which was defined as the time from the date of surgery to the date of recurrence, was less than 1 year in approximately 40–60% of patients in either cohort.

Overall Survival

OS after recurrence was compared among the three cohorts. After a median follow-up time of 380 days from the date of recurrence (319 days in 71 dead patients and 560 days in 18 alive patents), the median survival time (MST) was 287 days in cohort A, 451 days in B and 547 days in C. OS was significantly shorter in cohort A than in cohort C ($p = 0.0034$), while there was no significant difference between cohorts B and A or C, as shown in figure 1. In cohort A, the duration of S-1 adjuvant chemotherapy was <6 months in 11 patients, 6 to <12 months in 10 and 12 months in 9. No significant difference in OS (MST, 246 vs. 287 vs. 464 days; $p = 0.4963$) was observed according to the duration of S-1 adjuvant chemotherapy, as shown in figure 2.

Efficacy of First-Line Chemotherapy

Regimens of the first-line chemotherapy delivered after recurrence are shown in table 2. Nine patients (30.0%) in cohort A received S-1-based therapy (S-1 monotherapy [12, 13] in 3, S-1 plus cisplatin [14] in 3, S-1 plus irinotecan [15] in 3, S-1 plus paclitaxel [16] in 0), although 9 patients were treated with paclitaxel monotherapy administered in a weekly fashion [17] and 12 patients with irinotecan-based therapy (irinotecan monotherapy [18] in 5, irinotecan plus cisplatin [19] in 7). In cohort B, 5 patients (50.0%) received S-1-based therapy, with 4 patients being treated with paclitaxel monotherapy and 1 patient with irinotecan plus cisplatin. In cohort C, 42 patients (85.7%) received S-1-based therapy, 4 patients were given paclitaxel monotherapy and 3 patients were given irinotecan plus cisplatin. It seemed inevitable for various regimens to

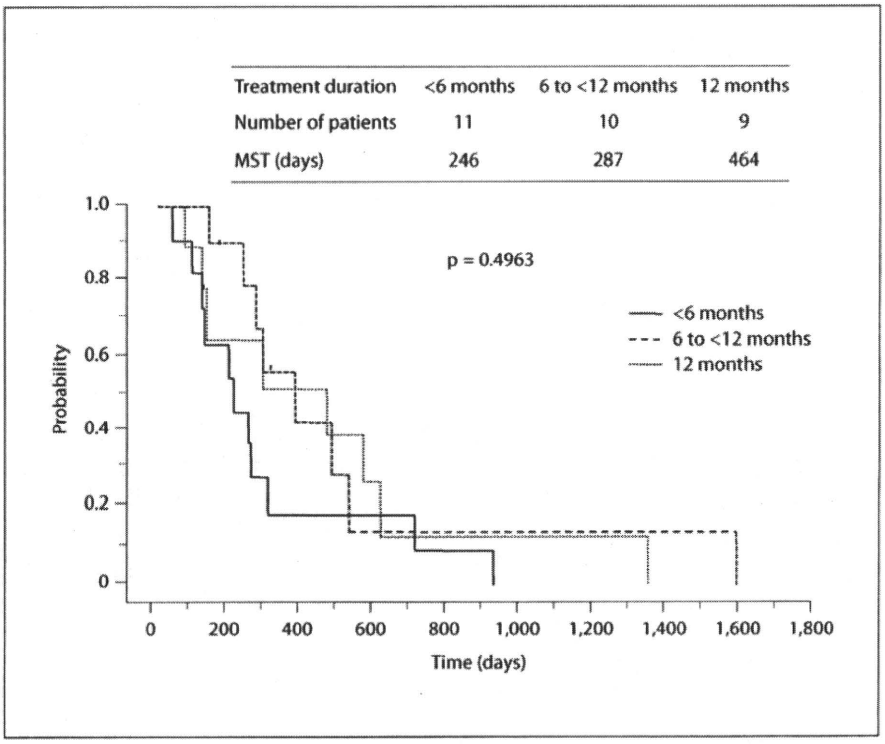

Fig. 2. OS according to the duration of S-1 adjuvant chemotherapy.

Table 2. Regimens of first-line chemotherapy after recurrence

	Cohort A (n = 30)	Cohort B (n = 10)	Cohort C (n = 49)
S-1-based therapy	9	5	42
S-1 monotherapy	3	3	26
S-1 + cisplatin	3	0	4
S-1 + irinotecan	3	1	7
S-1 + paclitaxel	0	1	5
Weekly paclitaxel	9	4	4
Irinotecan-based therapy	12	1	3
Irinotecan monotherapy	5	0	0
Irinotecan + cisplatin	7	1	3

have been given as the first-line treatment because it was obscure whether non-S-1-based therapy was more appropriate for patients relapsed after adjuvant S-1 or which should be chosen as a non-S-1 agent between paclitaxel and irinotecan for patients with recurrent gastric cancer. However, there was a tendency to prefer choosing S-1-based therapy as the first-line treatment after recurrence in cohort C, while non-5-FU regimens were more likely to be chosen in cohorts A and B. The best response to the first-line chemotherapy after recurrence was compared among these 3 cohorts, as shown in table 3. Response rates (RR) were 6.7% [95% confidence interval (CI) 0.8–22.1], 30.0% (95% CI 6.7–65.3), and 42.9% (95% CI 28.8–57.8) in cohorts A, B and C, respectively, with a significant difference between A and C (p = 0.0007). DCR were 50.0% (95% CI 31.3–68.7), 80.0% (95% CI 44.4–97.5) and 89.8% (95% CI 77.8–96.6) in cohorts A, B and C, respectively, with a significant difference between A and C (p = 0.0001).

Prognostic Factors for OS

The results of univariate and multivariate analyses of various factors, such as gender, age, histology, initial stage and presence of measurable lesion, number of metastatic sites, DFI and type of adjuvant chemotherapy for OS following recurrence are summarized in table 4. Among these, absence of a measurable lesion [hazard ratio 2.18 (95% CI 1.28–3.72)], presence of multiple metastatic sites [hazard ratio 2.89 (95% CI 1.28–6.52)] and S-1 adjuvant chemotherapy [hazard ratio 2.64 (95% CI 1.35–4.75)] were identified as significant independent factors for poor prognosis after recurrence.
