A pig model of reduced left ventricular (LV) function and remodeling or chronic heart failure with long survival after myocardial infarction (MI) has not been established. The aim of this study was to evaluate the pathophysiologic status of a pig model of old MI using a series of PET studies. **Methods:** Twenty-seven male farm pigs were divided into 2 groups: 7 animals in the control group and 20 animals that underwent a proximal coronary artery (CA) occlusion using an ameroid constrictor after distal CA ligation. A series of PET examinations was performed to assess LV volumes, LV functions, myocardial perfusion response to adenosine, and viability as water-perfusible tissue index. **Results:** The distal CA ligation inhibited arrhythmia during and after the operation, and a transmural anteroseptal MI, with an infarction area of $27\% \pm 5\%$ of the whole left ventricle, was generated with a survival rate of 75% at 4 mo. Wall motion evaluated by ¹⁸F-FDG PET was diffusely reduced, including the noninfarcted wall. Global LV ejection fraction as assessed by gated C¹⁵O PET was reduced ($39\% \pm 16\%$) in the group undergoing occlusion, compared with the control group ($66\% \pm 16\%$, $P < 0.05$). LV end-systolic (31.4 ± 9.2 cm³) and end-diastolic (52.7 ± 10.2 cm³) volumes were increased, compared with controls (15.2 ± 9.4 cm³, $P < 0.01$, and 41.7 ± 11.5 cm³, $P < 0.05$, respectively). Histology showed hypertrophy and development of microscopic fibrosis in noninfarcted myocardium. PET demonstrated the reduced myocardial perfusion response to adenosine and also reduced water-perfusible tissue index in remote segments. **Conclusion:** The pig model of old MI generated by the chronic proximal CA obstruction after distal ligation was characterized by LV dysfunction and remodeling, with a high survival rate.

Key Words: experimental model; PET; myocardial flow reserve; remodeling; regeneration therapy

Chronic heart failure (CHF) is an increasing health concern (1). Myocardial infarction (MI) is the cause of CHF in two thirds of the patients, and the morbidity and mortality remain high (2,3). The potential therapies, such as new class of pharmacologic agents and cell therapy (4), need to be tested in proper animal models to demonstrate the effects and outcome before initiating clinical trials. Dogs have been extensively used in heart research. Because the coronary arterial systems in dogs can develop collaterals quickly when myocardial ischemia occurs, it has been difficult to produce a large MI that typically introduces CHF with general characteristics of left ventricular (LV) remodeling (5).

Pigs have been considered better suited than dogs for pathophysiologic research of ischemic heart diseases, because the coronary system of pigs is more similar to that of humans (6). Tolerance of ischemia and denervation after ischemia in pigs is also similar to that in humans (6). Because of the delayed development of collaterals after occlusion, ligation of a peripheral part of the coronary arterial system generates a small MI (7). However, an experimental model of large MI introducing global LV dysfunction is difficult to develop, because sudden cardiac death (SCD) due to fatal arrhythmias and an intolerance of ischemia frequently occurs in pigs (8). The models of small MI made by the ligation of a peripheral part of the coronary arterial system demonstrate reasonably good survival rates but only for a small infarction. The model of small MI using a coronary ameroid constrictor (model MRI-2.50-TI; Research Instruments SW) has also demonstrated moderate SCD rates (6,8–13–15), but the animals develop primarily chronic ischemia or hibernating myocardium, without a significant amount of scar tissue. Thus, the limitations of current models are that the infarcted region is small and that the hearts are not developing a clinical picture of CHF with global LV dysfunction, LV dilatation, and remodeling.

On the other hand, Shen et al. (16) developed an experimental pig model of MI and heart failure. Sequential

ligation of distal and proximal coronary arteries was used to establish MI with a reasonable survival rate, and pacing tachycardia was used to achieve heart failure. However, this pig model was studied over only a short term (21 d) and required pacing tachycardia to cause CHF. There has been little evaluation of pathophysiology and no evidence of the presence of cardiac remodeling.

This aim of this study was to characterize the pig model of old MI. We first reinvestigated the technique of generating a pig model of relatively large MI causing global LV dysfunction and LV remodeling in segments remote from the infarcted region, by means of the sequential ligation of distal and proximal coronary arteries without the pacing procedures. We then evaluated the pathophysiologic characteristics of this animal model by comprehensively analyzing histology, LV volumes and LV function, myocardial perfusion response to adenosine, and perfusable tissue fractions (PTF) in the remote segment, using an advanced PET technique.

MATERIALS AND METHODS

Subjects

Male farm pigs, 3 mo old at the start of the study (weight range, 18–23 kg; mean weight \pm SD, 20 ± 1.2 kg), were used. The animals were divided into 2 groups. Group A consisted of 7 pigs without any operation and was designated as the control group (average body weight, 26 ± 2.4 kg). Group B consisted of 20 pigs that underwent occlusion using an ameroid constrictor (7); ligation of the distal left anterior descending coronary artery (LAD) was performed before the ameroid constrictor was used. Of the 16 pigs that survived for 4 mo after the operation, 7 underwent PET studies. The other 9 were assigned to tissue-regenerative projects. The average body weight of this group of 7 pigs was 42 ± 8.2 kg at the time of the PET scan.

Animals were maintained and handled in accordance with guidelines for animal research (17). The study protocol was approved by the local Committee for Laboratory Animal Welfare, National Cardiovascular Center, Osaka, Japan.

Permanent Occlusion Procedures

In group B, permanent occlusion was made at the proximal LAD using an ameroid constrictor (18) (Fig. 1) as follows. Pigs were preanesthetized by an intramuscular injection of ketamine hydrochloride (20 mg/kg; Ketalar [Diichi-Sankyo]) and xylazine hydrochloride (2 mg/kg; Celactal [Bayer HealthCare]). The animals were positioned supine, and a 22-gauge indwelling needle (Surflo F&F; Terumo) was inserted in the central vein of the auricle. A 3-way cock (Terufusion TS-TR2K; Terumo) was attached to the external cylinder of the indwelling needle and connected for continuous anesthetic injection. The animals were intubated with an endotracheal cannula (6 French; Sheridan) and then connected to an artificial respirator (Single Animal Volume Controlled Ventilators model 613 [Harvard Apparatus]) with a stroke volume of 200–300 cm³/stroke and frequency of 20/min. Propofol (6 mg/kg/h; Diprivan [Astra-Zeneca]) and vecuronium bromide (0.05 mg/kg/h; Musculux [Sankyo Yell Yakuhin Co., Ltd.]) were continuously infused using a syringe pump (Terufusion TE-3310N; Terumo). Then, the animals were fixed in a recumbent position so that the left thorax was exposed, and the

outer layer of skin and muscles between the third and fourth ribs was dissected. The distance between the third and fourth ribs was widened with a rib spreader to allow a direct view of the left auricle and LAD. The pericardium was dissected along the LAD, from the upper part of the left auricle (~6 cm), to expose the myocardium around the LAD. The LAD on the proximal side, below the left auricle from the myocardium, was exfoliated for approximately 1 cm. A lidocaine hydrochloride jelly (Xylocaine jelly; Astra-Zeneca) was applied to anesthetize the area.

A complete ligation was first made on the distal LAD (no. 9), immediately after the second diagonal branch, using a suture (2-0; Nescosuture) approximately 20 min before the ameroid constrictor was fastened. An ameroid constrictor (COR-2.50-SS; Research Instruments) was then fastened using sutures as displayed in Figure 1. To enhance the effect of the ameroid constrictor, 2 additional suture strings were loosely rounded at the site of the ameroid so that these strings were located between (below) the ameroid constrictor and arterial wall.

PET Procedures

After fasting overnight, the pigs were sedated with ketamine hydrochloride (20 mg/kg) and xylazine hydrochloride (2 mg/kg) by intramuscular injection. Anesthesia was induced and maintained with intravenous propofol (6 mg/kg/h) and vecuronium bromide (0.05 mg/kg/h). The animals were intubated and mechanically ventilated with a mixture of 25% oxygen and 75% nitrogen at 10 mL/kg plus 50 mL/stroke at 20 strokes/min. Catheters were placed in the femoral artery to monitor the arterial blood pressure and in the femoral vein to infuse H₂¹⁵O or ¹⁸F-labeled FDG. Systolic and diastolic blood pressure, heart rate, and arterial blood gases were monitored.

A series of PET scans was obtained using an ECAT-HR tomograph (CTI Inc.). The blood-pool images were obtained after the animals inhaled 2.7 GBq of C¹⁵O gas (19). Arterial blood samples were taken every minute during the C¹⁵O scan, and their radioactivity concentration in the whole blood was measured. Additional electrocardiogram-gated C¹⁵O images were obtained (16 gates). After 12–15 min of ¹⁵O radioactivity decay, 7 dynamic H₂¹⁵O PET scans were acquired at intervals of 12–15 min. The first and the last scans were obtained without pharmacologic stress, and the second through sixth scans were obtained during intravenous infusion of adenosine (100, 200, 400, 600, and 800

FIGURE 1. Ligation of LV LAD. Distal LAD after second diagonal branch was ligated, and 30 min later ameroid constrictor was placed at proximal LAD. Two suture strings were inserted between ameroid constrictor and arterial wall to make occlusion complete. LCX = left circumflex artery.

[only for group A] $\mu\text{g}/\text{kg}/\text{min}$). The 6-min dynamic scan of 26 frames (12×5 , 8×15 , and 6×30 s) was started when radioactivity appeared in the right ventricle. Furthermore, another PET scan using ^{18}F -FDG was acquired using a euglycemic hyperinsulinemic clamp (20,21). For this study, insulin (4 mIU/kg/h) and glucose (5–8 mg/kg/min) were continuously infused over 2 h, and then approximately 111 MBq of ^{18}F -FDG was intravenously injected. The blood glucose was 109 ± 10.6 , 105 ± 3.8 , and 107 ± 10.0 mg/dL at the time of ^{18}F -FDG injection. PET images were acquired dynamically for 60 min, and the images acquired during the last 30 min were used for further analysis. An additional electrocardiogram-gated scan was obtained for 30 min to estimate myocardial wall motion and wall thickening.

After the PET scans, coronary angiography was undertaken to confirm the occlusion of LAD. A portable angiographic camera (Digital Mobile Imaging System OEC Series 9800; GE Healthcare U.K. Ltd.) was used with the contrast medium (Omnipaque 300; Daiichi-Sankyo).

Histologic Analysis

At the end of the study, pentobarbital sodium was administered, and animals were euthanized. The animals' hearts were then excised and sliced at a thickness of 10 mm to correspond to PET images (22). The slices were stained with Masson trichrome and hematoxylin and eosin. The surface area of the infarcted LV wall on the stained slices was calculated according to a previously describe procedure (22). The length of the infarcted zone, including both transmural and nontransmural infarction, was measured on each of the stained slices along the LV wall. The defect surface area was then calculated as a summation of the defect length multiplied by the slice interval. The cell and microvascular structures were also analyzed. In particular, development of fibrosis, cell enlargement, and degeneration of the vascular network were visually estimated. The analysis was masked from the other analyses.

Data Analysis

The extravascular tissue density images (g/mL) were calculated by subtracting the C^{15}O blood volume from the transmission images (23). The relative images of myocardial blood flow (MBF) and water-PTF (g/mL) were also generated from the dynamic H_2^{15}O images (22,23). The relative accumulation of ^{18}F -FDG was calculated using validated techniques (24). The regions of interest were placed in the anterior wall and lateral-anterior wall, which corresponded to the MI and normal-tissue regions, respectively. The regions of interest were then copied to other images, and the quantitative parameters of regional MBF (mL/min/g), PTF (g/mL), and arterial blood volume V_a (mL/mL) were calculated using nonlinear least-squares fitting as described previously (22,23). These calculations were done for all H_2^{15}O PET studies to estimate baseline MBF and the adenosine-based responses both in MI and in non-MI regions.

The water-perfusable tissue index (PTI) (23,25,26), which was defined as the fraction of water-perfusable tissue over total tissue, was calculated by dividing PTF by the extravascular tissue density images. This calculation was done for each myocardial region and compared between the infarcted anterior wall and normal posterior-lateral wall regions. The obtained values were also compared with control subjects.

The LV ejection fraction and cardiac output were evaluated by counting the total counts within the LV area from the typical

electrocardiogram-gated C^{15}O images shown in Figure 2. The wall motion was analyzed using electrocardiogram-gated ^{18}F -FDG images. The wall motion score was divided into 4 levels (normal, 0; hypokinetic, 1; akinetic, 2; and dyskinetic, 3) and defined for the anterior wall and contralateral (lateral-posterior) wall regions.

The surface area of the infarcted LV wall on the ^{18}F -FDG and PTF images was calculated as described previously (22). A significant defect was defined as a value less than 50% of that in the control region, which was defined in the contralateral region, indicating preserved ^{18}F -FDG, preserved PTF, and elevated MBF during adenosine. The myocardial midlines were then traced along the 50% of peak count boundary of the C^{15}O blood volume images at each slice (22). The surface area of the defect was calculated as a summation of the defect length multiplied by the slice interval. These defect surface areas were compared with those obtained from the stained slices.

All data were presented as mean \pm SD. Pearson correlation and linear regression analyses were used to evaluate relationships between the 2 values. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Survival Rates of Animal Groups

No adverse events were detected in group A; in group B, 4 pigs (20%) died within a month and an additional pig 1 mo after that. Thus, the total survival rate at 4 mo was 75% in group B. Severe arrhythmia occurred in all animals in group B during the operation. The arrhythmia and fibrillation, introducing the sudden cardiac death, were significantly suppressed at approximately 20 min after ligation of the distal LAD. Figure 3 displays the survival rates of the pigs that underwent the operation.

Of the pigs in group B that survived for 4 mo, 7 were selected for further characterization and imaging studies. These 7 animals were compared against the animals in group A, on which no operation was performed. The characteristics of the 2 groups at the time of the imaging

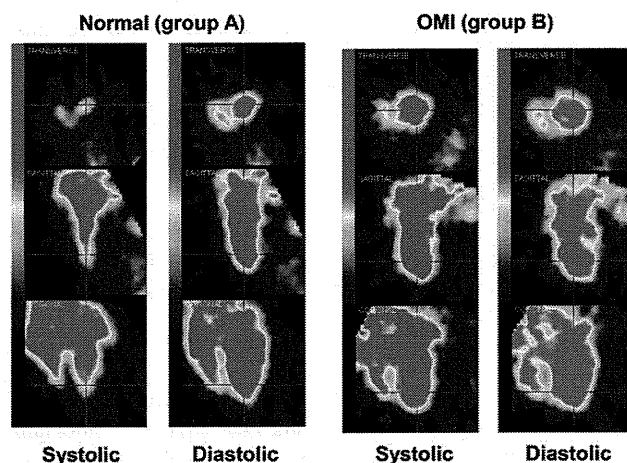

FIGURE 2. Typical images obtained from electrocardiogram-gated PET scans with C^{15}O inhalation at end-systolic and end-diastolic phases. OMI = old MI.

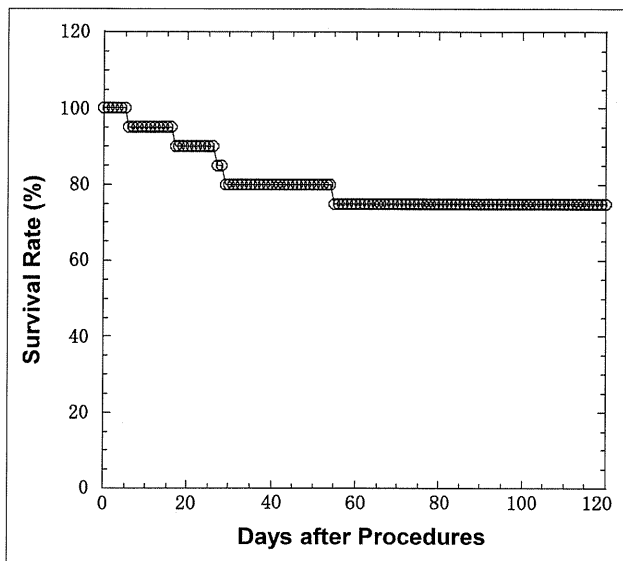

FIGURE 3. Survival rates for group B after ameroid constrictor was placed.

studies are displayed in Table 1. Because the animals in group B were allowed to grow after operation, they were larger at the time of the imaging studies.

Characteristics of Groups

Table 1 shows the hemodynamic data for the animals in groups A and B. Compared with group A, group B showed a significantly reduced heart rate and diastolic blood pressure and, thus, rate-pressure product. In addition, the global LV ejection fraction measured with gated $C^{15}O$ PET in group B was significantly reduced ($39\% \pm 16\%$ [24%–59%] in group B vs. $66\% \pm 16\%$ [46%–91%] in group A, $P < 0.01$). LV end-systolic volume in group B was

significantly increased ($31.4 \pm 9.2 \text{ cm}^3$ in group B vs. $15.2 \pm 9.4 \text{ cm}^3$ in group A, $P < 0.01$), and LV end-diastolic volume was also significantly increased ($52.7 \pm 10.2 \text{ cm}^3$ in group B vs. $41.7 \pm 11.5 \text{ cm}^3$ in group A, $P < 0.05$). Increased end-systolic and end-diastolic volumes are also clearly visible in Figure 2. Systolic blood pressure and diastolic blood pressure, as well as rate-pressure product, were reduced during adenosine study in both groups. Heart rate was increased in group A but not in group B. Other parameters such as hemoglobin concentration (g/dL), percentage saturation of arterial O_2 , $PaCO_2$ (mm Hg), and PO_2 (mm Hg) were not significantly different between the 2 groups. Table 2 shows detailed hemodynamic parameters and the results from the histologic analysis for each individual animal in group B. Wall motion score was reduced (akinesis-dyskinesis or 2–3) in the anterior wall, which includes the area of MI. The wall motion score was also reduced diffusely in all animals and indicated hypokinesis (grade 1) in the infarct-remote posterolateral wall. The coronary angiography demonstrated complete occlusion of the LAD in all animals in group B. As shown in Figure 4, no clear collateral circulation existed.

Imaging Results

The myocardial perfusion ($H_2^{15}O$) and metabolism (^{18}F -FDG) images at the mid ventricular plane and their corresponding slices after histochemical staining for the animals in group B are displayed in Figure 5. In all animals, clear signs of MI were detected in the anterior wall. The surface area of the MI was $13.7 \pm 4.3 \text{ cm}^2$, which corresponded to $27\% \pm 9\%$ of the whole left ventricle. Both PTF and ^{18}F -FDG images visually agreed well with the stained slices. Moreover, the ^{18}F -FDG images agreed well with the qualitative PTF images in all animals. The spatial distribution and size of the developed MI are visually reproducible

FIGURE 4. Example of coronary angiogram in animal with ameroid constrictor (arrow) (group B).

among the animals. Myocardial hypertrophy was visible in the wall regions remote from the infarcted area. In group B, the posterior-lateral wall thickness estimated from histochemical staining was 16 ± 1 mm (Table 2), which was significantly greater than that of group A (12 ± 1 mm; Table 1) ($P < 0.001$).

Further analysis of the size of the infarcted region is displayed in Figure 5B. We excluded 1 animal whose ¹⁸F-FDG PET images demonstrated high accumulation at the anterior LV area (and therefore a smaller value in the defect surface area), which was attributed to the adhesion or inflammation between the myocardial and chest walls. Thus, the defect area on histology showed intersubject variation of approximately 20%. The results of both ¹⁸F-FDG and PTF image analysis and histochemical analysis agreed well (Fig. 5B). Baseline and adenosine-stimulated MBF were also clearly blunted in the anterior wall in the animals in group B (Fig. 6A). Interestingly, abnormally reduced adenosine flow response also was detected in the myocardial regions remote from the MI in group B, whereas the baseline flow values were normal.

Further analysis of myocardial PTF and PTI values—indices of PTF—revealed that these values were significantly reduced in the infarcted anterior wall in group B (Fig. 6B). PTI was also moderately but significantly (~10%) reduced in the remote myocardial wall in group B.

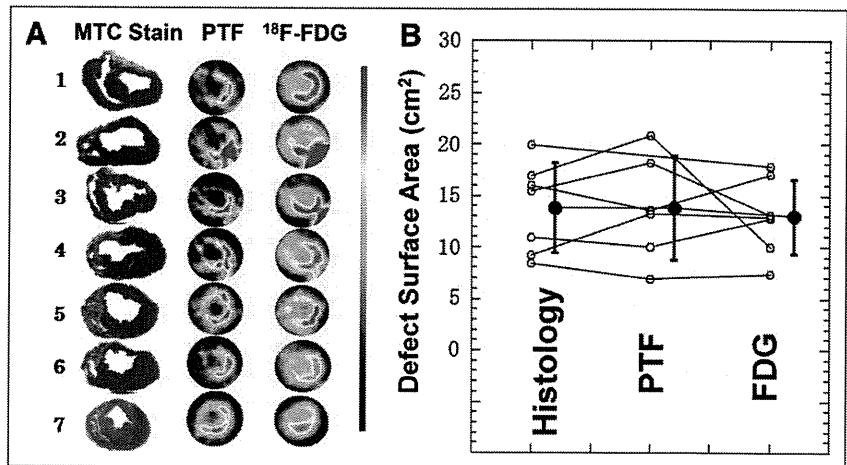

Histologic Analysis

Histologic analysis did not show any signs of MI in group A, but transmural anterior wall MI was apparent in all animals in group B. Hypertrophy was detected in the posterior wall of group B in all animals. Multinuclear muscle cell breeding (Fig. 7A) and hyperplasia of blood vessels (Fig. 7B) were also visible in all animals in group B, mostly in the subendocardial regions. Denaturation necrosis with epicardial fibrous change and hypertrophy has also been seen in the lateral-posterior wall regions of group B (Fig. 7C).

DISCUSSION

This study demonstrated that 75% of pigs with old MI generated by the 2 steps of LAD ligation survived more than 4 mo. Such a long survival has never, to our

FIGURE 5. (A) Histologic, PTF, and ^{18}F -FDG slices at middle level of left ventricle in 7 animals of group B. Spatial distribution and size of MI are visually reproducible among animals. Myocardial hypertrophy was visible in remote myocardial wall regions. (B) Comparison of defect surface areas obtained from histologic stained slices with PET images using ^{18}F -FDG and PTF. MTC = Masson trichrome.

knowledge, been accomplished in any studies of pig heart disease. The size of MI reached approximately 27% of the whole left ventricle, causing the remodeling and global LV dilatation (significantly increased LV end-systolic and end-diastolic volumes) to be associated with reduced global LV function. PET with C^{15}O and ^{18}F -FDG showed that regional LV wall motion was impaired not only in the infarcted region but also in the myocardial areas remote from the MI. PET also demonstrated reduced MBF reactivity in remote regions in addition to the infarct area. PTI was also reduced in the remote region, suggesting development of microscopic fibrosis. Moreover, other findings from histology indicated the existence of abnormalities in the noninfarcted area remote from the MI. These results indicate that this animal model may be close to human CHF after MI.

Shen et al. (16) adopted additional pacing tachycardia in pigs after sequential coronary artery ligations and observed global LV dysfunction, claiming that CHF was introduced. The present study is similar to the study by Shen et al. (16) but is based on only sequential coronary artery obstructions

accomplished with acute distal coronary artery occlusion followed by a chronic proximal coronary occlusion with an ameroid constrictor, causing similar LV dysfunction. Of note was the better survival rate (80% at 1 mo, 75% at 4 mo) demonstrated in the current report than in any previous report (6,8-12,14,16), including Shen et al. (73.3% at 21 d). In addition, it has not been confirmed whether such a good survival rate at 21 d could last more than 4 mo after producing global LV dysfunction with MI. Our preliminary experiment, independently performed on 69 farm pigs, demonstrated that when the proximal LAD was occluded by the ameroid constrictor alone, 45 pigs (65%) died within a month, and the total survival rate was 30% at 4 mo. This survival rate is significantly smaller than the rates from the present study.

The reason why animals with MI acquired such good survival is not fully understood. However, it was clearly observed that the ligation of the peripheral coronary artery before the gradual occlusion of the main trunk of the LAD apparently inhibited the fibrillation during the operation. This procedure is obviously effective at protecting against

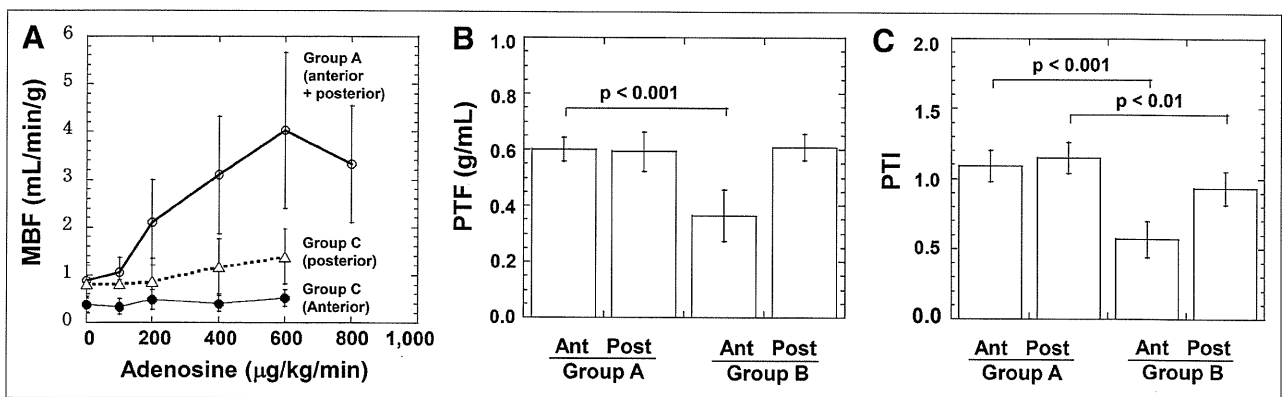

FIGURE 6. Results from PET studies. (A) Regional MBF as function of adenosine dose. In group A, MBF increases with increasing adenosine dose. In infarcted anterior wall of group B, MBF is reduced at rest and does not respond to adenosine. In posterior wall region, adenosine reactivity was significantly reduced. (B and C) Comparison of water-PTF (B) and water-PTI (C). Both were reduced in anterior wall of group B. PTI was also reduced in posterior wall in group B. Ant = anterior; Post = posterior.

FIGURE 7. Typical images of histologic staining obtained from group B. Hypertrophy with multinuclear muscle cell breeding (A), hyperplasia of blood vessels shown as arrows (B), and denaturation necrosis often seen in subendocardial regions, as in this picture (C), are typical findings.

fatal arrhythmias. This preconditioning effect is supported by the experiments of Moses et al. (27), in which ischemic preconditioning of the distal coronary artery protected cardiac muscle through a mechanism involving the potassium channels of mitochondria and myocytes. There may be contributions from other preconditioning factors (9,28–30) that associate with increased tolerance of ischemia. Another mechanism could be associated with the modulation of sympathetic tone. It has been reported that regional heterogeneity in myocardial cellular mechanisms (responsible for myocardial cellular depolarization) and repolarization in hibernating myocardium (12) can induce ventricular fibrillation (9). Inhibition of such heterogeneous myocardial cellular mechanisms or control of modulated sympathetic tone could be another possible explanation.

The present study used a gradual total occlusion of the proximal of LAD, as evidenced by the coronary angiography (Fig. 4), and thus caused an MI of approximately 27% of the total myocardium. The global LV ejection fraction in group B was significantly reduced (39% vs. 66% in controls), showing that LV systolic function was impaired in group B. Both histology and PET had concordant findings. The baseline MBF in the MI area was reduced and was not responding to adenosine administration. This finding is reasonable because the infarcted tissue should have reduced capillary density, and the resistive vessels do not respond to any vasodilating stimulation. The physical extent and size of the MI were reproducible among the individual animals. This feature is important when this animal model is applied to evaluate various new pharmaceuticals or various regenerative therapeutic trials.

The noninfarcted myocardium developed clear signs of remodeling, such as hypokinesis, hypertrophy, and the accumulation of fibrotic tissue in the remote myocardial wall, and significantly decreased PTI values, a marker of residual fractionation of water-perfusible tissue. The baseline MBF was preserved, but reactivity to the adenosine was blunted, even at a maximum dose of 600 $\mu\text{g}/\text{kg}/\text{min}$. This reduced reactivity could be related to the degeneration of small arteries, possibly caused by enlargement of myo-

cytes and development of moderate denaturation necrosis and fibrosis.

This study demonstrated that physiologic status and physical extent of MI can be evaluated using the non-invasive technique of PET. The defect surface area identified with ^{18}F -FDG was identical to that identified with PTF, and both agreed well with the results of histology. Furthermore, microscopic degeneration can be characterized as reduced reactivity of quantitative myocardial perfusion to adenosine. The PET-derived PTI, which is known to indicate the absolute fraction of non-scar tissue within the area (22), was reduced not only in the infarcted anterior wall but also in the remote region by 10%. As demonstrated in recent studies (31–34), the reduced PTI in a control region is thought to be caused by the development of microscopic fibrosis.

In this study, left-atrial and LV pressure analyses have not been measured, because the aims of this study were to create a long-survival pig model of MI and global LV dysfunction with remodeling, characterize this model using PET, and compare these parameters with histology before making a complete model of CHF after MI in pigs. One limitation of this study was that, because of technical reasons in our laboratory at the initiation of this study, it was difficult to measure left-atrial and LV pressures.

CONCLUSION

Our pig model of postinfarction global LV dysfunction was characterized by a high survival rate and large MI, with clear signs of cardiac remodeling, as demonstrated by PET and histology. This animal model might contribute to investigations of MI and new therapies for cardiac remodeling in MI.

ACKNOWLEDGMENTS

We thank the staff of the Department of Investigative Radiology of National Cardiovascular Center for invaluable technical assistance. This study was supported by a re-

search grant from New Energy and Industrial Technology Development Organization (NEDO), Japan, and grants for translational research and nanomedicine from the Ministry of Health, Labor and Welfare (MHLW), Japan.

Long-Term *In Vivo* Magnetic Resonance Imaging Tracking of Endothelial Progenitor Cells Transplanted in Rat Ischemic Limbs and Their Angiogenic Potential

Carlos A. Agudelo, Ph.D.,¹ Yoichi Tachibana, Ph.D.,¹ Teramoto Noboru, B.Sc.,²
Hidehiro Iida, Ph.D.,² and Tetsuji Yamaoka, Ph.D.^{1,3}

Stem cell therapy has been used to repair ischemic tissues in the limbs, in myocardial infarctions, and in the brain. To understand the mechanisms of healing, a contrast agent capable of inducing sufficient magnetic resonance (MR) contrast would be useful in providing fundamental information about the cell migration and incorporation into the ischemic tissue. A magnetic resonance imaging contrast agent composed of dextran and gadolinium chelate was synthesized. Hydroxyl groups of dextran were activated with 1,1'-carbonylbis-1H-imidazole and reacted with propanediamine to obtain aminated dextran. This modified polymer was then reacted with mono-N-succinimidyl 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate, then with fluorescein isothiocyanate, and finally reacted with gadolinium chloride solution (Dex-DOTA-Gd³⁺). Endothelial progenitor cells (EPCs) were selected as a stem cell model for magnetic resonance imaging tracking. Cells were isolated from the bone marrow harvested from the femurs and tibias of rats. Dex-DOTA-Gd³⁺ was then introduced into the EPCs by electroporation. The intracellular stability and cytotoxicity of Dex-DOTA-Gd³⁺ were evaluated *in vitro*. Dex-DOTA-Gd³⁺-labeled EPCs were transplanted into a rat model of ischemic limb, and MR images were acquired. Dex-DOTA-Gd³⁺ was found to efficiently label EPCs over a long duration without significant cytotoxicity. This provides an MR signal sufficient for tracking the EPCs intramuscularly injected into the limb.

Introduction

RECENT PROGRESS IN STEM CELL isolation from different sources such as blood, bone marrow (BM), and adipose tissue, coupled with better understanding of their functions, has led to the development of new applications of stem cell transplantation therapies in areas such as cardiac regeneration,^{1,2} hind limb ischemia,³⁻⁵ and stroke.⁶ When implanting stem cells in ischemic tissues, the cells will likely differentiate into functional cells or release growth factors that act in a paracrine manner.⁷⁻⁹ A system for tracking the stem cells *in vivo* would provide insights into many basic and practical questions related to stem cell therapy, such as the mechanisms involved in migration, recruitment, mobilization, and incorporation of cells into tissue.⁷ Magnetic resonance imaging (MRI) is a noninvasive method that has the potential to reach the levels of sensitivity and resolution, which are necessary for detection of small quantities of cells and to determine their locations within ischemic tissues.

MRI tracking of cells labeled with iron oxide-based magnetic contrast agents has been used for visualization of many aspects of angiogenesis in different cell types such as the

hematopoietic and neural progenitor cells.¹⁰⁻¹² One of the advantages of labeling cells with superparamagnetic iron oxide particles (SPIO) is the high sensitivity obtained compared with that obtained with other contrast agents.¹³ Wilhelm *et al.* reported that SPIO-labeled cells can be detected in small quantities (30–60 cells in agarose gel) by high-resolution MRI.¹⁴ Other studies reported stem cell homing to the organs and the BM,¹⁵ differentiation and migration of oligodendrocyte progenitors into brain parenchyma, migration and incorporation of labeled cells to the sites of tumor angiogenesis,¹⁶ and magnetic guiding of the endothelial progenitor cells (EPCs) to a target site.¹⁴ However, despite the great advantages provided by SPIO labeling, some studies have reported certain disadvantages. Magnetic resonance (MR) signals in iron oxide-labeled cells transplanted into a mouse hind limb did not show significant differences from the day 1 to 28 post-transplantation; however, there is evidence for a progressive decrease in the cell number when monitored using genetically introduced bioluminescent signals.

Histological analysis confirmed that macrophages loaded with iron oxide particles were located between muscle

¹Department of Biomedical Engineering, and ²Department of Investigative Radiology Advanced Medical Engineering Center, National Cerebral and Cardiovascular Center Research Institute, Suita, Osaka, Japan.

³Japanese Science and Technology Agency—Core Research of Evolutional Science and Technology, Chiyoda-Ku, Tokyo, Japan.

bundles but no transplanted cells were detected near the macrophages.¹⁵ Therefore, one of the problems when labeling with iron oxide is the instability to remain in the cells *in vivo*, which can probably be termed as leakage. It is possible that the free SPIO are subjected to endocytosis by macrophages. A similar situation was described in iron oxide-labeled mesenchymal stem cells that were transplanted into a rat model of infarcted myocardium.¹⁶ In addition, iron oxide induces negative contrast in MRI, which, in some cases, can be difficult to attribute to the signal loss of the labeled cells, because of many other sources of negative contrast of MRI in the body.

Our group recently reported the development of a polymeric MRI contrast agent based on a gadolinium-chelated poly(vinyl alcohol).¹⁷ In this study, NIH-3T3 cells were labeled with the contrast agent via electroporation. Cell viability and proliferation were not affected by polymer labeling, and MR measurements showed that labeled cells could be clearly tracked *in vivo*. In this study, we selected EPCs as a stem cell tracking model. The EPCs isolated from the peripheral blood and BM have been used in the therapeutic angiogenesis of ischemic limbs, in stroke, and in myocardial infarction.^{18–25}

Advances in the techniques for visualizing EPCs, which are activated by cytokines at the site of injury, are imperative for understanding the mechanisms of proliferation, recruitment, mobilization, and incorporation of EPCs into the foci of vasculogenesis. Although the detection sensitivity of gadolinium chelates is generally lower than that of iron oxide, their positive contrast is easy to detect in a determinant tissue.^{26,27} Therefore, we synthesized a water-soluble gadolinium chelate as an alternative MRI contrast agent. This agent, called Dex-DOTA-Gd³⁺, was designed for labeling EPCs. Dex-DOTA-Gd³⁺ was delivered into EPCs by electroporation to investigate its feasibility for cellular imaging and its capability for tracking the fate of the cells *in vivo* over long periods. In addition, we defined a procedure for properly visualizing labeled EPCs transplanted into a rat model of ischemic limbs.

Materials and Methods

H-NMR measurements

Proton nuclear magnetic resonance (H-NMR) spectra were recorded using a 300-MHz 7.1-T NMR spectrometer (Gemini 2000/300; Varian Inc.). The concentration of paramagnetic species Gd(III) was measured by inductively coupled plasma atomic emission spectroscopy (Model 7510; Shimadzu Co., Kyoto, Japan).

Synthesis of Dex-DOTA-Gd³⁺

Amination of dextran (MW, 40 kD) was conducted as follows: dextran (10 mmol sugar unit) was dissolved in 60 mL of anhydrous dimethylsulfoxide followed by addition of 1,1'-carbonylbis-1H-imidazole (7.5 mmol). The reaction was allowed to proceed under a nitrogen atmosphere at room temperature for 4 h. 1,3-propanediamine (75 mmol) was then added to the resulting reaction mixture, which was then stirred overnight at room temperature. The reaction product was subsequently purified by dialysis (Spectra/Pore membrane; MW cut-off=10 kDa) in distilled water. The re-

maining solution was lyophilized, and dextran-diamine was obtained. About 1% of the total amino groups were reacted with fluorescein-5-EX, succinimidyl ester (FITC; Invitrogen, Molecular Probes®, Eugene).

¹H-NMR (D₂O): δ 4.99 (br,CHO₂), 3.605 (br,CHOH), 3.769 (br,CHOH), 5.2 (br,CHO), 3.253 (br,C(=O)NHCH₂), 2.88 (br,CH₂NH₂), 1.792 (br,CH₂CH₂CH₂), 3.53 (br,CHOH), 3.922–3.983 (br,CHCH₂).

Dextran-diamine was diluted in 60 mL of anhydrous dimethylsulfoxide and reacted with mono-N-succinimidyl 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetate (DOTA, 1 mmol of NH₂ in dextran-diamine: 1.2 mmol of DOTA) under a nitrogen atmosphere at room temperature for 1 day. The reaction mixture was purified in distilled water by using a dialysis membrane (Spectra/Pore membrane; MW cut-off=10 kDa). The final solution was lyophilized, and dextran-diamine-DOTA was obtained.

¹H-NMR (D₂O): δ 5.02 (br,CHO₂), 3.63 (br,CHOH), 3.77 (br,CHOH), 5.2 (br,CHO), 3.3 (br,C(=O)CH₂N), 3.51 (br,NCH₂C(=O)OH), 3.326 (br,C(=O)NHCH₂), br,CH₂CH₂N, 1.91 (br,CH₂CH₂CH₂), 3.92 (br,CHOH).

Dextran-diamine-DOTA was diluted in 50 mL of distilled water and treated with 2.2 mole equivalents of gadolinium chloride solution, which was added dropwise with stirring. After the stabilization of the solution with addition of 1 M NaOH to obtain a final pH of 6.6–7.0, the reaction product was stirred for 1 day at room temperature. After this, the reaction mixture was purified in distilled water by using a dialysis membrane (Spectra/Pore membrane; MW cut-off=10 kDa). The final solution was lyophilized, and dextran-DOTA-Gd³⁺ was obtained (Dex-DOTA-Gd³⁺).

MRI measurements

T₁-weighted images were obtained in a 1.5-T compact MRI system (MRmini; Dainippon Sumitomo Pharma) with a TR of 2000 ms and TE of 9 ms (FOV: 4×8 cm; matrix: 126×256; slice thickness: 1 mm; slice gap: 0 mm; number of slices: 35).

Isolation of EPCs

BM was flushed from the femurs and tibias of F344 rats (4-week-old males) after previous cytokine induced mobilization of BM-derived EPCs by subcutaneous injections of granulocyte colony-stimulating factor (Kirin Pharma) at 200 µg/kg/day over 5 days.^{28,29} CD34 and FLK-1 positive BM cells were isolated by magnetic beads (Streptavidin Microbeads; Miltenyi Biotec GmbH) coated with the antibodies CD34 and FLK-1 (sc-6251 and sc-7324; Santa Cruz Biotechnology, Inc.) and by using the biotin labeling kit NH₂ (Dojindo Molecular Technologies, Inc.). Cells were placed in fibronectin-coated dishes and cultured with an endothelial cell basal medium (EBM-2) supplemented with EGM-2 SingleQuots (Clonetics Lonza).¹⁸

Histological identification of EPCs

One week after isolation, the cells were detached using ReagentPackTM (Clonetics Lonza), and 1×10⁵ cells were placed in fibronectin-coated dishes (3.5-mm glass bottom dish; Matsunami Glass IND., Ltd.). Fluorescent staining of adherent cells was used to confirm the EPC phenotype. EPCs were incubated with 1,1'-dioctadecyl-3,3',3'-tetramethylindocarbocyanine perchlorate-labeled acetylated LDL (DiI-acLDL,

10 $\mu\text{g}/\text{mL}$; Biomedical Technologies; $n=3$) at 37°C for 4 h.^{19,21,24} EPCs were further stained with fluorescein *Griffonia simplicifolia* lectin I, isolectin B4 (10 $\mu\text{g}/\text{mL}$; Vector Laboratories, Inc.; $n=3$) for 2 h.^{30,31} Additional staining with endothelial nitric oxide synthase was performed (eNOS; Santa Cruz Biotechnology, Inc.; $n=3$).³¹ After staining, the samples were viewed with a confocal microscope (Nikon Eclipse TE 2000-E; Nikon Corporation). Cells with positive fluorescence were identified as EPCs.^{19,21,30,31} Six days after implantation of double-labeled EPCs by using Dex-DOTA-Gd³⁺ and a Qtracker® cell 655 labeling kit (Molecular Probes; Invitrogen Detection Technologies, Eugene; labeling was performed according to the manufacturer's instructions), a rat was sacrificed to demonstrate that the MR images of the contrast agent Dex-DOTA-Gd³⁺ when inside the cells actually correspond to the EPCs transplanted into the ischemic limb. Adductor muscle was dissected and subsequently embedded in Tissue-Tek for freezing (Sakura Finetechnical Co. Ltd.). Samples were then observed with a confocal microscope (Nikon Eclipse TE 2000-E; Nikon Corporation) ($n=20$; thickness, 8 μm). Paraffin sections of the excised tissue were then stained for macrophages as follows: Frozen sections were thawed, and the tissue was fixed in acetone. Sections were then washed in TBS buffer (50 mM Tris-HCl buffer containing 0.01% Tween-20 and 0.15 M NaCl) and treated with 0.6% H₂O₂ in 80% methanol at room temperature for 20 min. After washing in TBS buffer, the samples were incubated with mouse antirat CD68 (AbD Serotec) as a primary antibody at 4°C overnight. Sections were washed in TBST and stained with Histofine® Simple Stain MAX PO (Nichirei Biosciences, Inc.) and a second antibody at room temperature for 30 min. After washing in TBST, the tissue was incubated in 3,3'-diaminobenzidine tetrahydrochloride solution until a brown reaction product appeared.

Determination of capillary density

To quantify the effect of transplanted-labeled cells on neovascularization, an assessment was performed by measuring the number of capillaries highlighted by alkaline phosphatase (AP) staining within 36 randomly chosen fields under a light microscope (Nikon Coolscope II, Nikon corporation) in sections taken from the ischemic hind limb (12 measurements/rat) at day 35. Tissue specimens were taken from the adductor and semi-membranous muscles. Capillary density was compared with the nonischemic limb. Frozen sections of tissue (8 μm) were stained with AP substrate kit III (Vector laboratories, Inc.) to detect capillary endothelial cells.^{32,33} Additional sections were stained for von Willibrand factor (polyclonal rabbit antihuman) (Dako LSAB System-HRP for use on rat specimens; DakoCytomation) to further confirm the phenotype of the endothelial cells.

Cell labeling by electroporation

After isolation, the EPCs were cultured for 2 months (cells were used in the fourth passage for all experiments) in fibronectin-coated dishes and cultured with EBM-2 supplemented with EGM-2 SingleQuots (Clonetics Lonza) at 37°C in 5% CO₂. Afterward, 5×10^5 cells were counted, placed in 60-mm dishes, and cultured for 1 day. Cells were then washed with phosphate-buffered saline solution (PBS; Invitrogen) and cultured in 3 mL of EBM (phenol red-free; Clonetics

Lonza) for 30 min. Dex-DOTA-Gd³⁺ was subsequently added to the medium at a concentration of 10 mM, and electrical pulses were applied to the cells by using a CUY-21 electroporator (NEPPA GENE) under the following conditions: field strength: 300 V/cm, number of pulses: 10, and pulse duration: 5 ms. Cells were then cultured for 1 h and washed several times with PBS.

Dex-DOTA-Gd³⁺-labeled EPCs were divided and placed into fibronectin-coated dishes for further microscopy analysis (35-mm dishes, 27-mm quartz bottom, 1.2×10^5 per dish; $n=30$). To verify whether Dex-DOTA-Gd³⁺ leakage from the cells occurred after electroporation, the cells were washed with PBS and treated with 1 mL of lysis buffer (25 mM Tris; pH 7.8, 2 mM 1,2-diamino-cyclohexane-N,N',N'-tetraacetic acid, 10% glycerol, and 1% Triton X-100). After 1 h of incubation at 37°C , 100 μL of the resulting solution was placed in a 96-well plate, and the fluorescence intensity was measured with a fluorometer ($n=10$; excitation: 430 nm, emission: 540 nm; Wallac 1420 ARVO SX; Perkin-Elmer Life Sciences). With the known quantity of Gd in the polymer, the Gd inside the cells could be determined by linear regression analysis of the known fluorescence intensity of the cell lysate versus the fluorescence intensity of the Dex-DOTA-Gd³⁺ at different concentrations.

Cytotoxicity

Cytotoxicity was analyzed by a lactate dehydrogenase cytotoxicity test (Wako Pure Chemical Industries, Ltd.; performed according to the manufacturer's instructions) after coculturing 10^4 EPCs with different concentrations of Dex-DOTA-Gd³⁺ for 24 h. Additionally, the tetrazolium salt (WST-1) was used to measure cell proliferation and viability (Premix WST-1 cell proliferation assay system; Takara BIO Inc.). Dex-DOTA-Gd³⁺-labeled and nonlabeled EPCs were placed in 12-well plate fibronectin-coated dishes (4×10^4 cells/well). The Premix WST-1 ready-to-use solution was added to the wells (100 μL solution/mL of medium), and the cells were incubated at 37°C under 5% CO₂ for 24 h. The absorbance was measured, and the cell quantity was calculated using a linear regression analysis of the fluorescence intensity of nonlabeled EPC in a determined number. Samples were collected thrice per week over a period of 10 days ($n=6$).

Relaxivity

T_1 relaxation was estimated for each gadolinium complex. Longitudinal relaxation times (T_1) were measured by a combination of measurements made in a large NMR tube (650 μL of distilled water to dilute the polymer to different concentrations) and in a small tube (containing 50 μL of benzene-D₆). An attenuator was used to obtain the signal of water protons. Samples were measured in a 300-MHz (7.1-T) NMR spectrometer (Gemini 2000/300; Varian Inc.) by using an inversion recovery technique with 19 inversion times, ranging from 1 to 5000 ms at room temperature (25°C). A typical 180° pulse was for 19 μs . T_1 values were calculated by a least-square fitting analysis of the signal intensities measured at 19 inversion times values in an exponential fashion. The relaxivity of the gadolinium complex was determined by a linear regression of $1/T_1$ versus the concentration of the gadolinium complex.

Rat ischemic limb model

Male F344 rats (8-week-old) were anesthetized with isoflurane (1.5% in the air). The left femoral artery and vein and their branches were ligated and excised completely through a skin incision. The femoral artery and vein were excised from their proximal origin as a branch of the external iliac artery to the distal point where it bifurcates into the saphenous and popliteal arteries.³⁴ Rats ($n=8$) were injected in 3 places with a total of 150 μL of Bolheal® containing Dex-DOTA-Gd³⁺-labeled EPCs inside the muscle at the inguinal region where the femoral artery and vein were excised. Injections were applied as follows: To allow normal movement of the cell through the muscle, 6.3×10^6 labeled cells in 50 μL of Bolheal component A (thrombin, 250 units/mL) were intramuscularly injected in three different places in the abductor and quadriceps (total, $1.8\text{--}2.0 \times 10^7$ cells), and 50 μL of Bolheal component B (fibrinogen, 80 mg/mL) was then injected at the same sites to temporarily immobilize the cells (gelation occurred in the muscle). Ischemic limb controls ($n=8$) were injected with 150 μL of Bolheal without cells.

Statistical analysis

All data are expressed as means \pm SD. Statistical significance was evaluated using an unpaired two-tailed Student's *t*-test for two variables. Differences were considered significant when *p* values were less than 0.05.

Results

MRI contrast agent

To develop a suitable MRI contrast agent for EPCs, we selected dextran (MW=40 KDa) because of its biocompatibility, rapid clearance in the body,³⁵ biodegradability,³⁶ and approval by the U.S. Food and Drug Administration (Fig. 1). Inductively coupled plasma atomic emission spectroscopy revealed that 19.5% of OH groups reacted with DOTA-Gd in the contrast agent structure, which corresponds to $m=48$ and $n=199$.

Figure 2a shows the MR images of Dex-DOTA-Gd³⁺ aqueous solutions at different concentrations. MR contrast agents shorten the longitudinal relaxation time T_1 value,

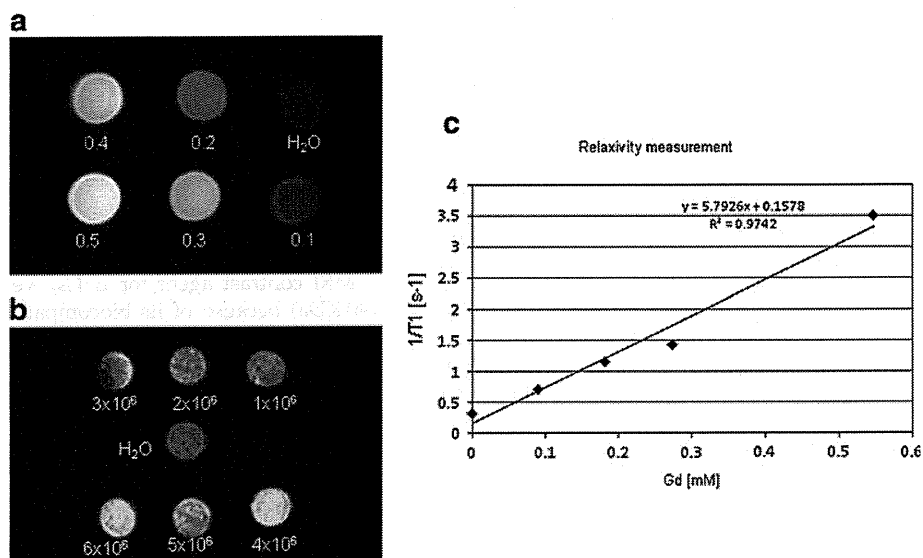

FIG. 1. Synthesis of MRI contrast agent. Schematic structure of Dex-DOTA-Gd³⁺, which consists of a dextran derivative modified with the gadolinium (III) chelate DOTA-Gd³⁺. MRI, magnetic resonance imaging.

2000 ms; TE, 9 ms; image acquisition matrix, 128×256 ; and $0.12 \text{ pg Gd}/\text{cell}$. (c) Relaxivity measurements of Dex-DOTA-Gd³⁺. T_1 was measured using a combination of an NMR tube ($650 \mu\text{L}$ of distilled water diluting the polymer to different concentrations) and a small tube containing $50 \mu\text{L}$ of benzene-D₆. An attenuator was used to obtain the signal of water protons. EPCs, endothelial progenitor cells; NMR, nuclear magnetic resonance.

which is defined as the time constant of the exponential recovery of proton spins to their equilibrium along an applied field after disturbance. The relaxivity (R_1) for Dex-DOTA-Gd³⁺, which represents the reciprocal of the relaxation time per unit of Gd concentration in s^{-1}/mM , was determined by measuring the longitudinal relaxation time T_1 values of several aqueous solutions by NMR and plotting $1/T_1$ versus the polymer concentration. Dex-DOTA-Gd³⁺ showed a relaxivity value of $5.8 \text{ s}^{-1}/\text{mM}$ (Fig. 2c), which, in comparison with approximate values of about $4.2 \text{ s}^{-1}/\text{mM}$ for DOTA-Gd and $3.8 \text{ s}^{-1}/\text{mM}$ for gadolinium-diethylenetriaminepentaacetic acid (DTPA-Gd),^{37,38} represents an increase of 38% and 52.6% over the relaxation value. Therefore, an enhancement of visualization of the resolution in MR images with Dex-DOTA-Gd³⁺ as a contrast agent is possible in comparison with the standard Gd³⁺ and Magnevits®. MR images of Dex-DOTA-Gd³⁺ aqueous solutions show an increase in signal intensity with regard to an increase in the concentration of the polymer (Fig. 2a). This increase is due to a reduction in the longitudinal relaxation time. Moreover, images show that the Gd complex has the capacity to return to its equilibrium state after radio frequency excitation. It can be seen that Dex-DOTA-Gd³⁺ MR images obtained at a

concentration of 0.2 mM are visually different from MR images of distilled water.

Labeling of EPCs

The phenotype of the EPCs was then confirmed by immunostaining with DiI-acLDL, and staining with lectin and eNOS (Fig. 3). All cells were confirmed as the EPC phenotype based on their capacity to incorporate acetylated low-density lipoprotein, to bind lectin, and to bind endothelial nitric oxide synthase throughout the process of obtaining images (Fig. 3).^{30,31} Both FLK-1 and CD34 are expressed by all hematopoietic stem cells and EPCs, but cease to be expressed during hematopoietic differentiation.^{18,19}

EPC cells were labeled with Dex-DOTA-Gd³⁺ by means of electroporation and placed into agarose hydrogel. Figure 2b shows MR images of EPCs containing Dex-DOTA-Gd³⁺ in $100 \mu\text{L}$ of agarose hydrogel. The amount of labeled cells necessary to obtain differences in contrast with regard to water was found to be 1×10^6 ($1.11 \times 10^{-10} \text{ mmol Gd}$), and the quantity of gadolinium incorporated into each cell was 0.12 pg of Gd. Cytotoxicity was analyzed by a lactate dehydrogenase cytotoxic test. Percentages of viable cells labeled

FIG. 3. Phenotype identification of the isolated EPCs. One week after isolation, fluorescent staining of the adherent cells was used to confirm the EPC phenotype. Cells were incubated with DiI-acLDL, isolectin B4, and eNOS. After staining, the samples were visualized with a confocal microscope. The cells demonstrated positive fluorescence, which indicates the EPC phenotype. Scale bar = $50 \mu\text{m}$. eNOS, endothelial nitric oxide synthase. Color images available online at www.liebertonline.com/tea

with Dex-DOTA-Gd³⁺ at different concentrations are shown in Figure 4a. This clearly shows that for Dex-DOTA-Gd³⁺ concentrations lower than 15 mM, cell viability is as high as 90%, whereas higher concentrations of Dex-DOTA-Gd³⁺ were found to be slightly toxic, but with a range between 70% and 80% cell viability.

Therefore, we selected a polymer concentration of 10 mM to label the cells, because this concentration has low toxicity while providing an adequate quantity of gadolinium to achieve the required T₁ shortening and high resolution for tracking labeled cells. Consistent with the previous results, the WST-1 assay performed with 10-mM polymer concentration revealed that EPCs were not affected by the contrast agent at least within 10 days after electroporation when cells achieved maximum confluence. No statistical differences were identified between the proliferation of nonlabeled EPCs and Dex-DOTA-Gd³⁺-labeled EPCs.

To analyze the distribution and stability of the contrast agent inside the cells, the Dex-DOTA-Gd³⁺-labeled cells were cultured for 25 days. As seen in Figure 4b, the EPCs exhibit a remarkably high degree of intracellular labeling with the cytoplasm containing large amounts of contrast agent. Interestingly, no further transport in the nuclei was

observed 25 days after labeling. Figure 4c shows the Dex-DOTA-Gd³⁺ concentration inside cells with regard to the culture period and cellular proliferation rate.

The quantity of polymer remained stable for 25 days after electroporation. This suggests that Dex-DOTA-Gd³⁺ did not leak out of the cells during the culture period, and that the cells grew well. The differences detected from day 1 to 25 were not statistically significant (*p* > 0.05), demonstrating stability of Dex-DOTA-Gd³⁺ labeling.

In vivo tracking of EPCs

Having demonstrated successful cellular MR imaging of EPCs by means of Dex-DOTA-Gd³⁺, we wanted to determine the efficacy of our MRI contrast agent for detecting and tracking EPCs in an *in vivo* rat model of ischemic hind limb. Immediately after inducing ischemia, we injected rats with Dex-DOTA-Gd³⁺-labeled EPCs in the adductor and quadriceps muscle in the inguinal region where the femoral artery and vein were excised (Bolheal was used to temporarily immobilize cells, as indicated in the Methods section). Animals were imaged thrice per week to determine the fate of the transplanted cells in the tissue. Figure 5 shows MR im-

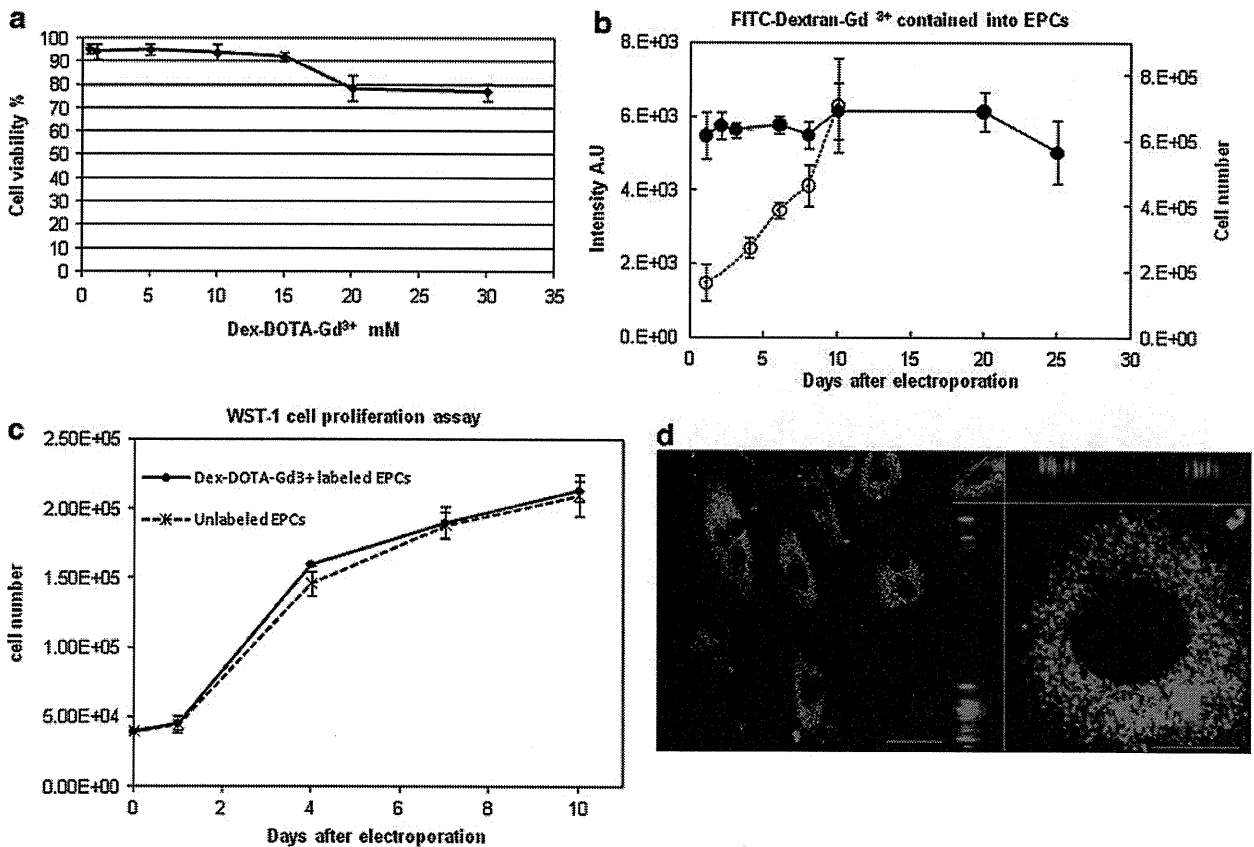

FIG. 4. (a) Viability of EPCs as measured by lactate dehydrogenase assay at different Dex-DOTA-Gd³⁺ concentrations. (b) Stability of Dex-DOTA-Gd³⁺ in EPCs after electroporation (solid mark) and cell proliferation (open mark). Fluorescence intensity mean (\pm SD) values are shown; no statistically significant differences were identified on the first day after electroporation (*n* = 5). *p* > 0.05. (c) Proliferation activity and viability of EPCs were assessed by WST-1 cell proliferation assay. The cell quantity was measured by its absorbance. The mean (\pm SD) values of cell number are shown; no statistically significant differences were identified between the labeled and unlabeled EPCs (*n* = 6). *p* > 0.05. ages obtained *in vivo* by using a 1.5-T animal MRI system within 20 days after transplantation. Cells could be clearly detected in the muscles and were observed to migrate for at least 16 days until the cells totally vanished at day 19. A rat was then sacrificed 6 days after transplantation, and the zone that appeared in the MR image was excised. The MR images in Figure 6a show that the cells are located in the adductor muscle. Frozen section slides revealed the presence of Qtracker 655-labeled EPCs in the ischemic area. During the development of the method for tracking EPCs *in vivo*, we observed that $5\text{--}6.3 \times 10^6$ labeled cells diluted in $50 \mu\text{L}$ of Bolheal were necessary to achieve cell imaging at least 14 days after transplantation.

Immunohistochemical staining for von Willebrand factor and (AP) of the removed muscles at 35 days revealed the presence of numerous capillary endothelial cells in the rats implanted with Dex-DOTA-Gd³⁺-labeled EPCs (Fig. 7a); capillary/muscle fiber ratios for this rat group markedly increased (two-fold, $p < 0.001$; Fig. 7b) relative to the ratio for the ischemic control group. There were no significant differences in capillary density between the ischemic control and the normal limb ($p < 0.05$; Fig. 7b). This blood flow recovery by the EPC transplantation suggests that our cell labeling system based on Dex-DOTA-Gd³⁺ electroporation does not affect cell viability, cell growth, or stem cell functions.

Discussion

BM-derived EPCs were successfully labeled with Dex-DOTA-Gd³⁺ by electroporation at 0.12 pg of Gd per cell. This extent of labeling is significantly lower than 12 pg of iron oxide/cell,¹⁶ but is nonetheless sufficient to achieve the signal enhancement required to provide good contrast in the body during MRI measurements. Several investigations on magnetic labeling of cells for MRI tracking *in vitro* and *in vivo* have shown that iron oxide nanoparticles are suitable for imaging stem cells.^{10,12,39} Nevertheless, more recent reports have called into question its use as a contrast agent, because of false-positive MRI signals, which lead to inconsistencies between a persistently positive MRI signal and histologically labeled cells.^{16,2,40-42}

Commonly used Gd complex contrast agents such as DOTA-Gd³⁺ and Magnevist exhibit relatively slow relaxation times in comparison to Dex-DOTA-Gd³⁺. This is because these contrast agents are simpler and low-molecular weight structures and need higher doses of contrast agent to accomplish the same resolution. The incorporation of DOTA-Gd³⁺ into dextran is likely to have caused an increase in the relaxation time due to a steric limitation imposed on the rotational movement of the polymer, which leads to an increase in the rotational correlation coefficient.^{43,44} In addition, DOTA-Gd conjugated to a biocompatible dextran carrier and the free Dex-DOTA-Gd³⁺ are expected to be rapidly cleared from the body and to have few interactions with the cell membrane because of their high solubility.

Our results demonstrate that Dex-DOTA-Gd³⁺ achieves intracellular labeling through electroporation, which is an essential condition for labeling cells. A membrane modified with a polymer will interfere with cell-cell interactions during the recruitment of cells in the mechanism of angiogenesis. A polymer in the cell membrane can be easily detached and may be taken up and transferred to other cells *in vivo*. The fluorescence intensity of the cell lysis solution suggests

that Dex-DOTA-Gd³⁺ remains stable in the EPCs for at least 25 days (Fig. 4c). A decrease in the fluorescence intensity indicates that the polymer has leaked out of cells during culture or that cells are dying, but no significant change in the fluorescence intensity has been demonstrated in the labeled EPCs. In addition, the cells showed a normal proliferation rate (during 10 days)⁴⁵ after Dex-DOTA-Gd³⁺ labeling by electroporation.

An additional cell proliferation activity and viability analysis was performed by using the WST-1 assay system. The results demonstrated that EPCs were not affected in the first 10 days after labeling by electroporation with Dex-DOTA-Gd³⁺ as a MRI contrast agent. No statistically significant differences were found between the proliferation of labeled and nonlabeled EPCs. After 10 days, the EPCs stopped proliferating and the quantity of cells remained stable. The viability claims are backed up with evidence for the first 10 days.

In vivo MR images indicate that the Dex-DOTA-Gd³⁺-labeled EPCs are perfectly detectable and that the fate of the cells can be followed within 16 days after transplantation with a cell density of $5\text{--}6 \times 10^6$ cells/0.05 mL (Fig. 5). Labeled cells totally faded after 19 days. This is likely due to cell bio-distribution during cell migration, which is probably caused by cytochemical attraction of EPCs via incorporation into newly formed vessels and may also be influenced by the release of pro-angiogenic factors in a paracrine manner.^{28,46-48} Moreover, it is likely that cellular proliferation occurs *in vivo*. This would reduce the concentration of the polymer inside the EPC cytoplasm and cause low contrast in the limb. The proliferation rate of the labeled cells *in vitro* indicated that after 10 days, the cells increased in number by three-folds, and the fluorescence intensity remained stable. This indicates that the concentration of Dex-DOTA-Gd³⁺ remained constant but the concentration per cell might be reduced by three-folds. Analogous to the *in vitro* results shown in Figure 2b, if the image contrast of 6×10^6 cells is reduced by three-folds, the signal intensity should be similar to the signal provided by 2×10^6 cells. If this intensity reduction is assumed *in vivo*, the 6.3×10^6 labeled cells transplanted into the ischemic limb 10 days after proliferation could then be tracked, because the Dex-DOTA-Gd³⁺ still has the capacity to produce a signal. At day 14 after implantation of labeled cells, the concentration of Dex-DOTA-Gd³⁺ underwent a four-fold reduction, which is the limit of the signal intensity provided by this contrast agent.

A rat was sacrificed 6 days after implantation of labeled cells. Muscles were carefully excised with particular attention to the location where MR images showed labeled cells. The presence of Qtracker 655-labeled EPCs localized in the neovascular zones of the ischemic limb ensures that MRI signals correspond to signals generated by the labeled cells (Fig. 6a). In addition, the number of macrophages found in the muscles (Fig. 6b) was insignificant, but was related to the obtained MR images or cells. This ensures that in contrast to cells loaded with iron oxide, the Dex-DOTA-Gd³⁺-labeled EPCs have not been subjected to endocytosis by the macrophages and are reliable for tracking of labeled cells over a long period.

Preliminary *in vivo* data suggest that Dex-DOTA-Gd³⁺-labeled cells were incorporated into sites of neovascularization and arranged into the capillary network. Direct local transplantation of labeled cells into the ischemic limb was found to quantitatively augment the capillary density in the ischemic limb *in vivo*.

FIG. 6. Identification of transplanted EPCs in the ischemic limb. (a) Six days after transplantation of Dex-DOTA-Gd³⁺-labeled and Qtracker® cell 655-labeled EPCs, a rat was sacrificed to demonstrate that MR images of the cells inside the muscle match the EPCs transplanted in the ischemic limb. (1) The MR image corresponds to the rat before sacrifice. The circle shows the location of labeled cells in the ischemic limb. (2) Frozen section of tissues dissected specifically in the area wherein the MR image indicated staining with Qtracker cell 655. (3) Differential interference contrast, and (4) Merge image. FIG. 7. Immunohistochemical staining of the nonischemic and ischemic limbs and determination of capillary density. Immunohistochemical staining for AP and vWF staining indicates viable endothelial cells. Five fields from two muscle samples from each animal ($n=9$) were randomly selected. (a) Capillary density is shown as the ratio of capillary to muscle fiber from frozen sections prepared from the muscles of ischemic limbs 35 days after transplantation of Dex-DOTA-Gd³⁺-labeled EPCs and ischemic controls. * $p < 0.05$ versus normal limb and ischemic control (b). AP, alkaline phosphatase; vWF, von Willebrand factor. Color images available online at www.liebertonline.com/tea

Conclusions

The use of MRI for tracking EPCs by using a novel contrast agent in the therapeutic angiogenesis of ischemic limb models would be extremely useful for the anatomical visualization of localization of the transplanted stem cells over a long period. Dex-DOTA-Gd³⁺ as an MRI contrast agent for imaging stem cells *in vivo* has consistently satisfied certain properties such as providing desired MRI contrast properties and *ex vivo* cell labeling before transplantation, generating high-degree and stable intracellular labeling, ensuring biocompatibility without affecting cell viability backed up with evidence for the first 10 days after electroporation, possessing proliferative and healing capacities, and remaining consistently detectable over long periods of time.
