Laminin

ABSTRACT

Protein O-linked mannose β 1,2-N-acetylglucosaminyltransferase 1 (POMGnT1) is an enzyme that transfers N-acetylglucosamine to O-mannose of glycoproteins. Mutations of the POMGnT1 gene cause muscle–eye–brain (MEB) disease. To obtain a better understanding of the pathogenesis of MEB disease, we mutated the POMGnT1 gene in mice using a targeting technique. The mutant muscle showed aberrant glycosylation of α -DG, and α -DG from mutant muscle failed to bind laminin in a binding assay. POMGnT1^{-/-} muscle showed minimal pathological changes with very low-serum creatine kinase levels, and had normally formed muscle basal lamina, but showed reduced muscle mass, reduced numbers of muscle fibers, and impaired muscle regeneration. Importantly, POMGnT1^{-/-} satellite cells proliferated slowly, but efficiently differentiated into multinuclear myotubes *in vitro*. Transfer of a retrovirus vector-mediated POMGnT1 gene into POMGnT1^{-/-} myoblasts completely restored the glycosylation of α -DG, but proliferation of the cells was not improved. Our results suggest that proper glycosylation of α -DG is important for maintenance of the proliferative activity of satellite cells *in vivo*.

1. Introduction

POMGnT1 is the glycosyltransferase that catalyzes the transfer of N-acetylglucosamine (GlcNAc) to O-mannose of glycoproteins, the second step of Ser/Thr O-mannosylation (Yoshida et al., 2001; reviewed in Endo and Toda,

2003). Mutations in the POMGnT1 gene cause muscle–eye–brain (MEB) disease, a rare autosomal recessive disorder characterized by congenital muscular dystrophy with elevated serum creatine kinase (CK) levels, severe visual failure, and gross mental retardation (Yoshida et al., 2001).

α -Dystroglycan (α -DG) is a heavily glycosylated glycoprotein and a well-known substrate of POMGnT1. Dystroglycan is encoded by a single gene (*DAG1*) and is cleaved into two proteins, α -dystroglycan (α -DG) and β -dystroglycan (β -DG), by posttranslational processing (Ibraghimov-Beskrovnaya et al., 1992). DGs are central components of the dystrophin-glycoprotein complex (DGC) at the sarcolemma, and α -DG was shown to serve as a cell surface receptor for laminin (Ibraghimov-Beskrovnaya et al., 1992), agrin (Gee et al., 1994; Campanelli et al., 1994), perlecan (Peng et al., 1998; Kanagawa et al., 2005), and neurexin (Sugita et al., 2001). In skeletal muscle, the laminin- α -DG linkage is thought to be critical for plasma membrane stability (recently reviewed in Kanagawa and Toda 2006). In MEB muscle, the α -DG core protein is preserved but hypo-glycosylated, and α -DG prepared from the muscle fails to bind laminin *in vitro* (Michele et al., 2002). Therefore, it is proposed that the disruption of the α -DG-laminin linkage is the main pathomechanism of dystrophic changes seen in MEB muscle.

To further elucidate the molecular pathogenesis of MEB disease, we generated POMGnT1-knockout mice using a gene targeting technique, and examined the mutant skeletal muscle. During our experiments, Liu et al. reported the generation of POMGnT1-deficient mice (Liu et al., 2006). The report showed severe muscle pathology, but the mechanism by which POMGnT1 deficiency causes muscle phenotype was not clearly shown. In this report, we report that POMGnT1-deficient mice show remarkably minimal signs of muscle degeneration and regeneration, but also show small muscle mass, reduced numbers of muscle fibers, and impaired muscle regeneration. POMGnT1-deficient myoblasts proliferate poorly *in vitro*. The proliferation was not improved by retrovirus vector-mediated POMGnT1 expression in POMGnT1^{-/-} myoblasts, suggesting that α -DG-laminin interaction *in vivo* is important for maintenance of the proliferative activity of satellite cells.

2. Results

2.1. Inactivation of the POMGnT1 gene in mice

We mutated the POMGnT1 gene by replacing exon 18 with a neomycin-resistance gene in mouse ES cells (depicted in Fig. 1). Two ES clones successfully entered the germline. Although there was no evidence of embryonic lethality, more than 60% of the homozygotes died within 3 weeks of birth. Survivors were smaller than their wild-type littermates (Fig. 3A) throughout life, but most of them had a normal life span. We confirmed that the POMGnT1^{-/-} mice completely lacked the POMGnT1 enzyme activity (Fig. 2A). A monoclonal antibody, VIA4-1, that reacts with the sugar moiety of α -DG gave no signal in either POMGnT1^{-/-} brain (Fig. 2B) or muscle (data not shown). A polyclonal antibody against α -DG core protein revealed that the POMGnT1^{-/-} brain expresses approximately 80 kDa α -DG protein, which is much smaller than that seen in the wild-type brain (ca. 110 kDa) (Fig. 2C). We next examined whether α -DG in POMGnT1^{-/-} brain binds laminin. Wheat germ agglutinin (WGA)-enriched brain protein from control and POMGnT1^{-/-} mice was separated on

SDS-PAGE gels, blotted onto a PVDF membrane, incubated with EHS laminin, and then bound laminin was detected by an anti-laminin antibody. α -DG in POMGnT1^{-/-} brain failed to bind to laminin (Fig. 2D).

2.2. POMGnT1^{-/-} muscle shows very mild dystrophic changes

Immunohistochemistry of cross-sections of tibialis anterior (TA) muscles showed that dystrophin and other members of the DGC complex were normally expressed at the sarcolemma of POMGnT1^{-/-} muscle (Fig. 3 and Table 1). Laminin α 2 chain was detected around POMGnT1^{-/-} muscle fibers. On H.E.-stained cross-sections, surprisingly, the POMGnT1^{-/-} muscle showed almost normal morphology. Central nucleation of myofibers indicates regeneration events in the past. In the TA muscles of 4-week-old wild-type mice, 0.25% of myofibers were centrally nucleated. In POMGnT1^{-/-} mice, 0.28% of the myofibers had central nuclei. In contrast, ca. 40–50% of myofibers of age-matched mdx mice were centrally nucleated. Even at 24 months of age, the percentage of centrally nucleated myofibers was lower (3.6%) in POMGnT1^{-/-} TA muscle, compared with age-matched wild-type TA muscle (9.0%). POMGnT1^{-/-} TA muscle also lacked other signs of degeneration and regeneration. Electrophoresis of muscle extracts on glycerol SDS-PAGE gels showed no difference in MyHC isoform composition of quadriceps and gastrocnemius muscles between POMGnT1^{-/-} and wild-type littermates (data not shown). In both wild-type and POMGnT1^{-/-} muscle, the muscle basal lamina was normally formed (Supplementary Fig. 1). Electron microscopy also showed that the sarcomere structures are almost normal in POMGnT1^{-/-} mice. We next examined the serum creatine kinase (CK) levels, an index of on-going muscle damage, in wild-type, POMGnT1^{-/-}, and age-matched mdx mice (Fig. 5). The serum CK levels of 5- to 20-week-old POMGnT1^{-/-} mice were slightly higher (av. 586 U/L, n = 10) ($p < 0.05$) than those of wild-type littermates (less than 100 U/L, n = 4), but were much lower than those of mdx mice (more than 5000 U/L, n = 3, $p < 0.01$). The serum CK levels of 2-year-old POMGnT1^{-/-} mice were still low (less than 300 U/L, n = 4).

2.3. Repetitive muscle injury causes more fibrosis and fatty infiltration in POMGnT1^{-/-} than in WT TA muscle

Dystroglycans expressed on the cell membrane of satellite cells are proposed to play an important role in muscle regeneration (Cohn et al., 2002). In addition, the average size of POMGnT1^{-/-} myofibers was smaller than those of wild-type myofibers (Fig. 4). Moreover, the number of myofibers is reduced in POMGnT1^{-/-} skeletal muscle of neonatal and adult POMGnT1 mice, suggesting proliferation defect of POMGnT1^{-/-} myoblasts (Fig. 4). To test the hypothesis, we damaged POMGnT1^{-/-} TA muscle by cardiotoxin (CTX) and examined their regeneration. After single cardiotoxin injection, POMGnT1^{-/-} muscle regenerated well like wild-type (data not shown). Next, we injected CTX into TA muscles of POMGnT1^{-/-} and heterozygous littermates three times at intervals of 2 weeks, or 1 week interval, and examined the muscle. We summarized the results in Fig. 6. POMGnT1^{-/-} muscle showed more fibrosis and

Fig. 1 – Targeted disruption of the mouse *POMGnT1* gene in embryonic stem (ES) cells. The successfully targeted allele lacks a 630 bp-genome fragment containing exon 18, and instead has a *neo* resistance gene. Recombination in ES cells was confirmed by Southern blotting with the probe shown by a shaded box. The nucleic acid numbers are from AB053221 in GenBank.

fatty infiltration, which is a sign of inefficient muscle regeneration, than *POMGnT1*^{+/-} muscle. Together with reduced numbers of myofibers in muscle, the results suggest that the function of satellite cells in *POMGnT1*^{-/-} skeletal muscle is impaired.

2.4. Defective proliferative activity of *POMGnT1*^{-/-} myoblasts

We next tested activation and proliferation of satellite cells on living myofibers isolated from wild-type and *POMGnT1*^{-/-}

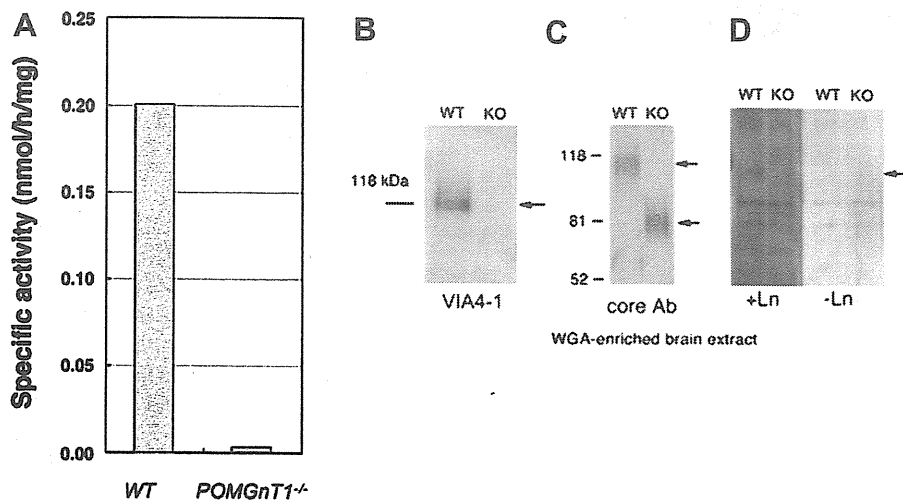

Fig. 2 – *POMGnT1*^{-/-} mice show undetectable *POMGnT1* enzyme activity and aberrant glycosylation of α -dystroglycan (α -DG) in *POMGnT1*^{-/-} mice. (A) The amount of *POMGnT1* activity is based on the amount of [³H]GlcNAc transferred from UDP-GlcNAc to mannosyl peptide. The reaction product was purified by reverse-phased HPLC, and the radioactivity was measured. (B) Wheat germ agglutinin (WGA) agarose-enriched brain extracts from wild-type (WT) or *POMGnT1*^{-/-} (KO) mice were resolved on a 7.5% SDS-PAGE gel, transferred to a PVDF membrane, and probed with anti- α -DG antibody, VIA4-1, which recognizes glycosylated α -DG. (C) The blot was incubated with polyclonal antibodies specific for α -DG core protein. The antibody detected ~110 kDa bands in wild-type brain extract, and 80 kDa bands in the brain extract of *POMGnT1*^{-/-} mice. (D) Laminin overlay assay showing that α -DG in *POMGnT1*^{-/-} brain does not bind laminin *in vitro*. +Ln, laminin was incubated with the blotted membrane. -Ln, without laminin.

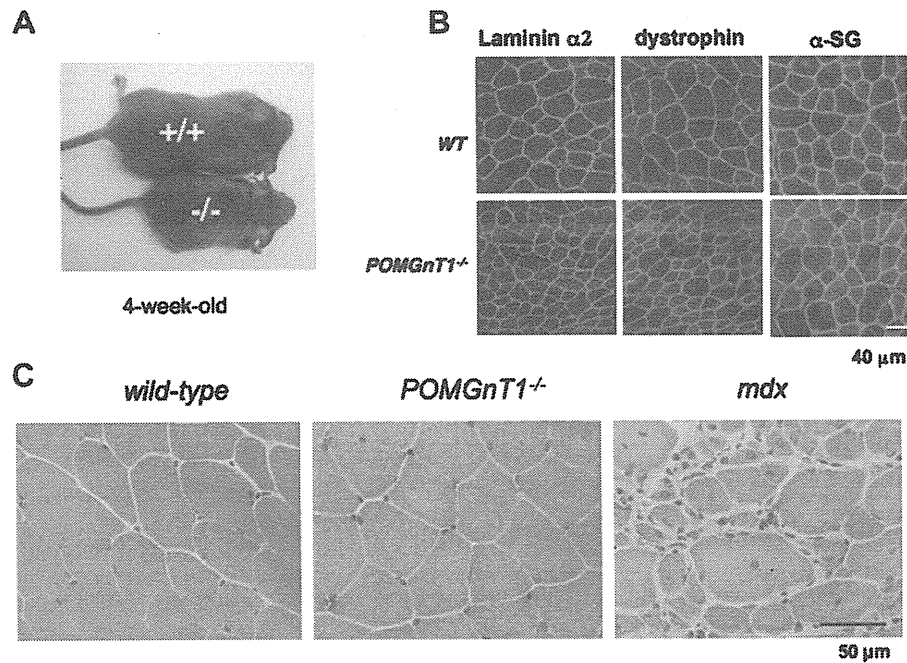

Fig. 3 – Remarkably mild dystrophic phenotypes of *POMGnT1*^{-/-} muscle. (A) A photo of representative 4-week-old wild-type (+/+) and *POMGnT1*^{-/-} (-/-) mice. *POMGnT1*^{-/-} mice are smaller than wild-type littermates. (B) Immunohistochemistry of wild-type (+/+) and *POMGnT1*-knockout (-/-). Laminin α 2 chain, dystrophin, and α -sarcoglycan are expressed normally on the sarcolemma of *POMGnT1*^{-/-} muscle. (C) Representative H.E. staining of cross-sections of the TA muscles from *POMGnT1*^{-/-}, wild-type, and age-matched dystrophin-deficient *mdx* mice. *POMGnT1*^{-/-} muscle shows minimal signs of degeneration and regeneration.

mice (Fig. 7). Three days after plating of single myofibers on Matrigel-coated 24-well plates in growth medium, the numbers of detached satellite cells (activated and proliferating satellite cells) were counted. In both extensor digitorum longus (EDL) (fast twitch muscle) and soleus (slow twitch muscle) muscles, the numbers of activated satellite cells and proliferating satellite cells (myoblasts) around the parental myofiber were more numerous in wild-type than in *POMGnT1*^{-/-} (Fig. 7). Furthermore, wild-type satellite cells migrate a little

faster than *POMGnT1*^{-/-} satellite cells on transwells (data not shown), although the difference was little. Therefore, our results suggest that *POMGnT1*^{-/-} satellite cells are activated more slowly or proliferate more slowly than wild-type. We next isolated satellite cells from hind limb muscles of wild-type and *POMGnT1*^{-/-} mice by a monoclonal antibody, SM/C-2.6, and flow cytometry (Fukada et al., 2007), and examined their proliferation rate. The total yield of satellite cells per gram of *POMGnT1*^{-/-} muscle tissue was nearly the same as those of wild-type muscle (data not shown). The percentage of Ki67-positive satellite cells (cycling cells) was less than 1% in both wild-type and *POMGnT1*^{-/-} mice, indicating that they are in the quiescent stage (data not shown). However, after plating wild-type and *POMGnT1*^{-/-} satellite cells onto Matrigel-coated 6-well plates at the same density, we found that *POMGnT1*^{-/-} satellite cells grew poorly in growth medium (Fig. 7B). The timing of activation (i.e. enlargement of the cytoplasm and MyoD expression) was the same with that of wild-type satellite cells (data not shown). Next, we cultured satellite cells on Matrigel-coated 24-well-plates in growth medium, and the cells growth was evaluated by MTT assay 1, 2, 3, 4, 5, 6, and 7 days after plating (Fig. 8). The assay revealed that wild-type myoblasts proliferated more rapidly than *POMGnT1*^{-/-} myoblasts *in vitro*. *POMGnT1*^{-/-} myoblasts fused normally to form multinucleated myotubes in differentiation conditions like the wild-type (data not shown), and there was no significant difference in the fusion index between wild-type (45%) and *POMGnT1*^{-/-} myoblasts (40%) ($p > 0.05$).

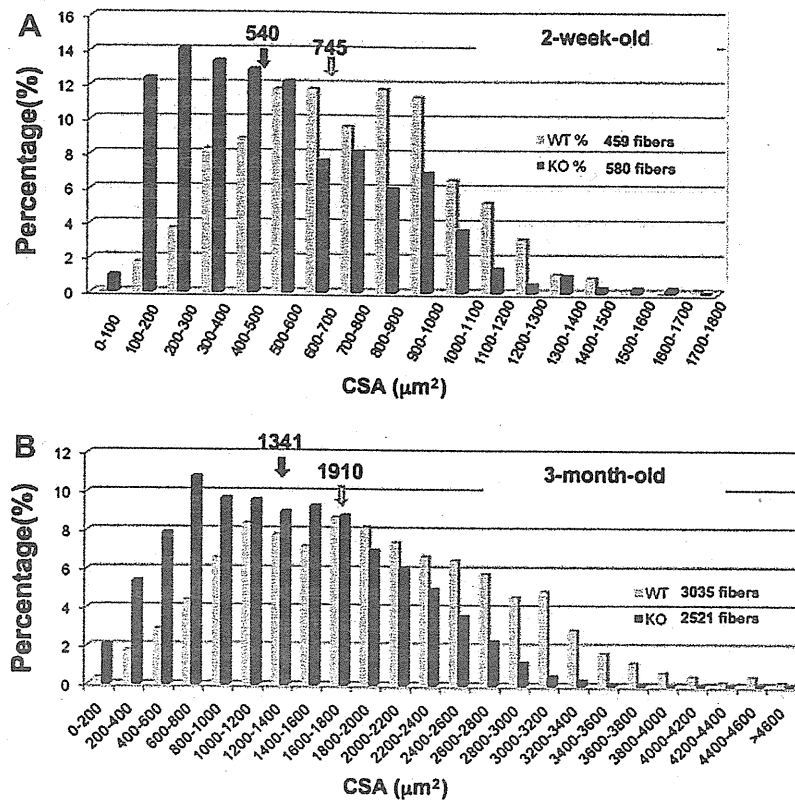

Fig. 4 – Cross-sectional area (CSA) of myofibers of *POMGnT1*^{-/-} and wild-type mice. (A) A representative frequency graph of CSA of rectus femoris muscles from 2-week-old *POMGnT1*^{-/-} (blue) and wild-type (light blue) littermates. The cross-sections were stained with anti-laminin $\alpha 2$ chain antibody. CSA of 459 *POMGnT1*^{-/-} fibers and 580 wild-type fibers were measured and plotted. X-axis indicates CSA (μm^2), and Y-axis indicates percentages. Arrows indicate the averages. The total number of myofibers was also reduced in *POMGnT1*^{-/-} mice (4169 vs. 3510). **(B)** The CSA of myofibers in TA muscles from 3-month-old *POMGnT1*^{-/-} (blue) and wild-type (light blue) male mice was plotted as in (A)). In (B), almost all myofibers were measured (3035 fibers in wild-type TA and 2521 fibers in *POMGnT1*^{-/-} TA).

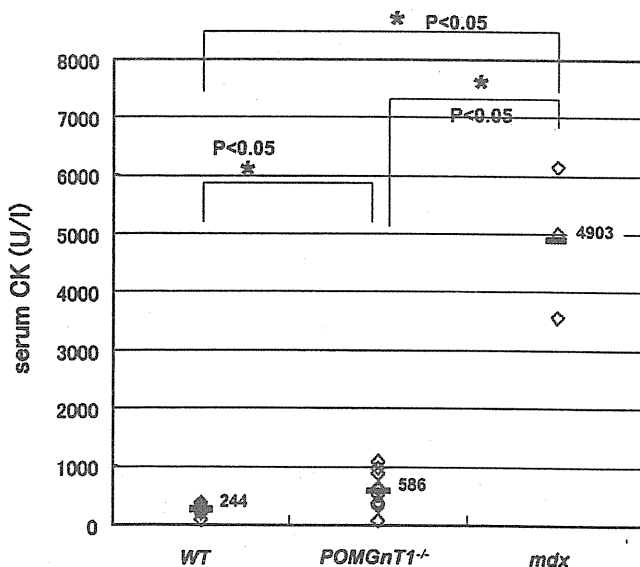

Fig. 5 – Serum CK levels of *POMGnT1*^{-/-}, wild-type, and *mdx* mice. Serum CK levels of 7–20 weeks old *POMGnT1*^{-/-} mice (5 males and 5 females), wild-type littermates (3 males and 1 female), and three male *mdx* mice were measured and plotted on the graph with average. * $p < 0.05$.

Next, we examined whether restoration of the expression of the *POMGnT1* gene in mutant myoblasts improved their proliferation. To this end, we prepared a retrovirus vector, (pMX-*POMGnT1*-IRES-GFP) expressing human *POMGnT1* and GFP. The recombinant retrovirus successfully restored O-mannosyl glycosylation of α -DG (Fig. 7A), but the proliferation rate was not changed (Fig. 8B).

2.5. Cell growth signaling in *POMGnT1*^{-/-} myoblasts

It was previously reported that enhanced expression of $\alpha 7\beta 1$ integrin ameliorates the development of muscular dystrophy and extends longevity in $\alpha 7\text{BX}2\text{-mdx/utr}^{-/-}$ transgenic mice (Burkin et al., 2001; Burkin et al., 2005), suggesting that integrin compensates for the function of α -DG in skeletal muscle to some extent. Therefore, we next examined the expression of $\beta 1$ -integrin in wild-type and *POMGnT1*^{-/-} myoblasts (Supplementary Fig. 1). Western blotting, however, showed no difference between the $\beta 1$ -integrin protein levels in wild-type and *POMGnT1*^{-/-} myoblasts (Supplementary Fig. 1A). Furthermore, FACS analysis showed similar levels of $\beta 1$ integrin expression on the surfaces of myoblasts (Supplementary Fig. 1B). We then examined the activation levels of Akt and GSK-3 β , both of which are involved in the

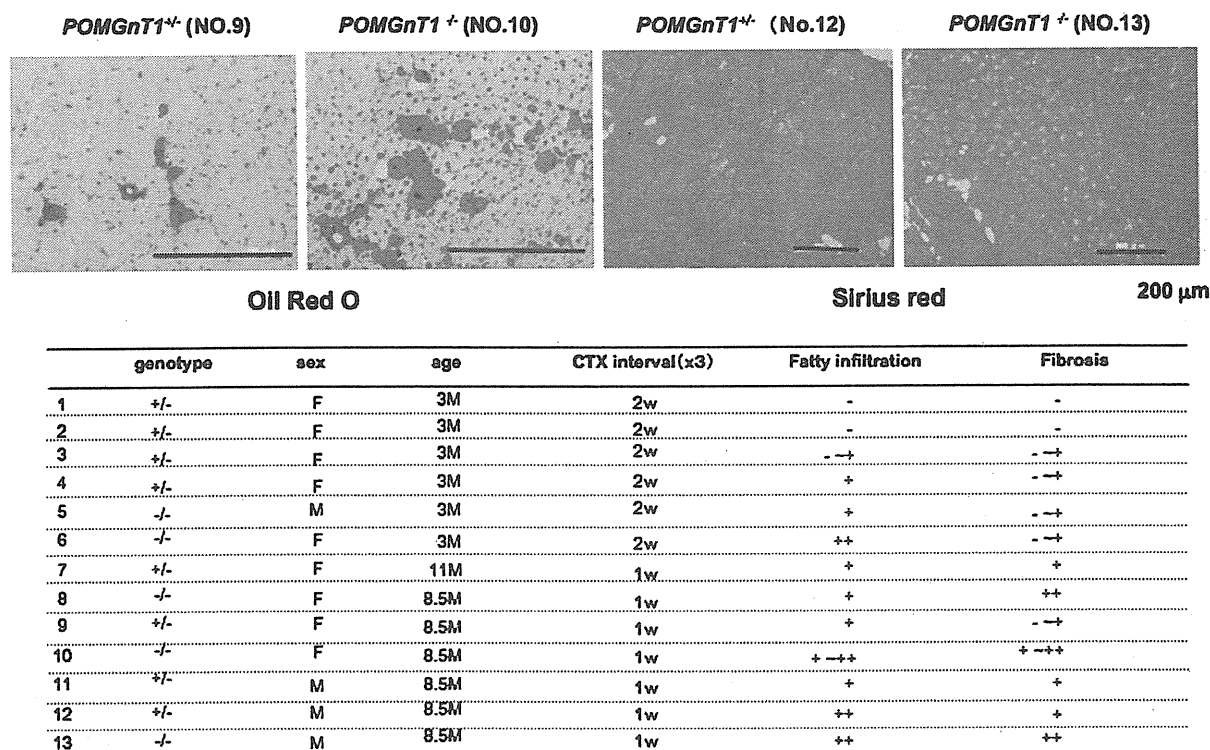

Fig. 6 – Impaired muscle regeneration of $POMGnT1^{-/-}$ mice. upper panel: representative Oil red O-stained or Sirius red-stained cross-sections of TA muscles of $POMGnT1^{-/-}$ ($-/-$) and $POMGnT1^{+/-}$ ($+/-$) mice after three rounds of degeneration/regeneration evoked by cardiotoxin injection. One week after the last CTX injection, TA muscles were dissected, sectioned by a cryostat, fixed, and stained. lower table: Summary of fatty infiltration and fibrosis in regenerated muscles. regulation of cell survival and proliferation. The levels of phosphorylation of these two kinases in $POMGnT1^{-/-}$ myoblasts were similar with those in wild-type myoblasts (Supplementary Fig. 1C). Consistent with these observations, TUNEL assay indicated that apoptosis is rare both in $POMGnT1^{-/-}$ and wild-type muscles (data not shown).

3. Discussion

In this study, we showed that in spite of mild muscle degeneration, the $POMGnT1^{-/-}$ satellite cells have much lower proliferative activity than wild-type satellite cells. The defect was not recovered by restoration of normal glycosylation of α -DG in mutant satellite cells. Together with the reduced sizes and the reduced numbers of myofibers of neonatal and adult $POMGnT1^{-/-}$ mice, these observations suggest that deficiency of $POMGnT1$ enzymatic activity impairs the functions of satellite cells.

3.1. Two mouse models of muscle-eye-brain (MEB) disease

Our $POMGnT1^{-/-}$ mice are the second mouse model of MEB disease. The first one was generated by gene trapping with a retroviral vector inserted into the second exon of the mouse $POMGnT1$ locus (Liu et al., 2006). As described in the literature, the phenotype is similar to ours with some

differences. Our model shows much milder muscle phenotypes than the previously reported model, but also shows much a lower survival rate in the postnatal stage than the first model does. This would be due to more severe developmental abnormalities of the central nervous system of our mouse model, including disruption of the glia limitans, abnormal migration of neurons, and reactive gliosis in the cerebral cortex (manuscript in preparation), although these are also observed in the first model (Yang et al., 2007; Hu et al., 2007).

Mutation of the $POMGnT1$ gene is the cause of muscle-eye-brain disease (MEB) (Yoshida et al., 2001), which is characterized by severe congenital muscular dystrophy (Voit and Tome, 2004). Although glycosylation of α -DG was completely perturbed in our model, the $POMGnT1^{-/-}$ muscle showed only marginal pathological changes. Furthermore, $POMGnT1^{-/-}$ muscle showed normally formed muscle basal lamina on EM. These observations are in sharp contrast to the condition in humans. One possibility is that in the mouse, molecules other than α -DG are involved in the linkage of the sarcolemma with the extracellular matrix proteins, stabilizing the plasma membrane. As a candidate molecule, we examined β 1-integrin expression in $POMGnT1^{-/-}$ muscle, but found that the level was not up-regulated. Therefore, the mechanism that explains this discrepancy remains to be clarified in a future study.

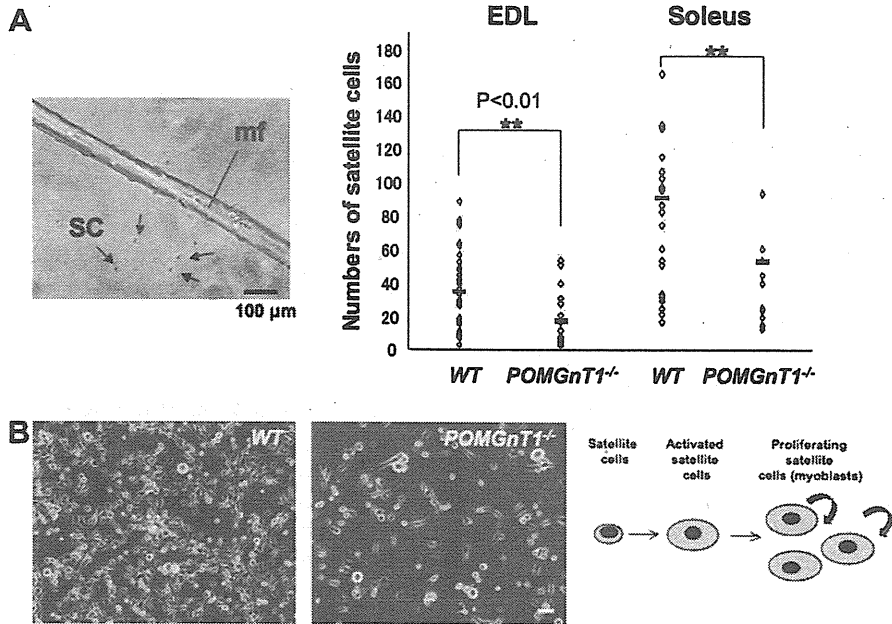

Fig. 7 – Activation and proliferation of satellite cells from WT and *POMGnT1*^{-/-} mice. (A) Isolated myofibers were plated on Matrigel-coated 24 well-plates at one myofiber per well. Three days later, activated satellite cells (SC, arrows) around the parental fiber (mf) were counted and plotted. Small horizontal bars indicate the average number of activated/proliferating satellite cells originating from a myofiber from three independent experiments. Student's t-test. ***p* < 0.01 (wild-type vs. *POMGnT1*^{-/-} mice). (B) Satellite cells from WT and *POMGnT1*^{-/-} mice 7 days after plating onto Matrigel-coated 24-well-plates at 2.5×10^3 cells/well. Scale bar, 100 μ m.

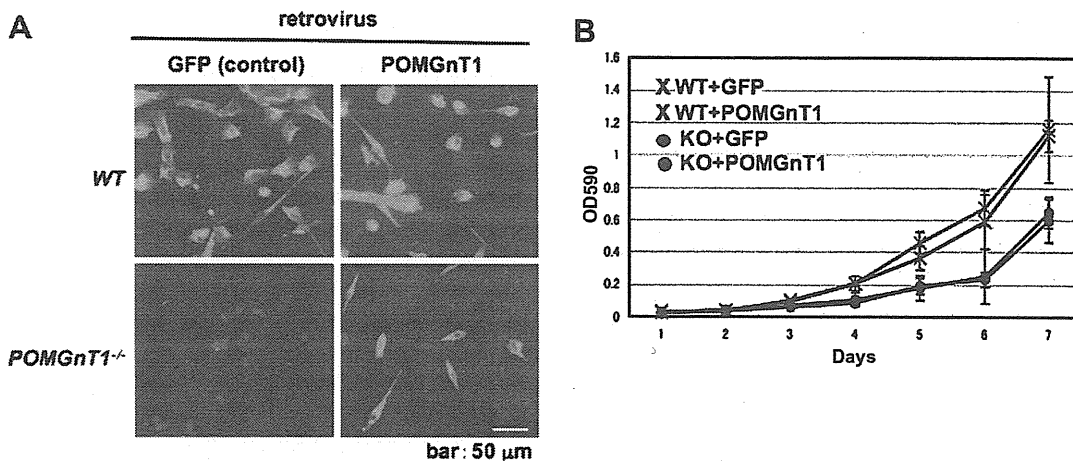

Fig. 8 – Restoration of *POMGnT1* expression in *POMGnT1*^{-/-} myoblasts does not improve proliferation of cells. (A) Wild-type (WT) and *POMGnT1*^{-/-} myoblasts were transduced with a retrovirus expressing both *POMGnT1* and GFP (*POMGnT1*) or only GFP (GFP, control), and the FACS-purified transduced cells were stained with anti-glycosylated α -DG monoclonal antibody (VIA4-1; red) and DAPI (Nucleus, blue). Note that the glycosylation of α -DG in *POMGnT1*^{-/-} myoblasts was completely recovered by a retrovirus vector expressing *POMGnT1*. (B) MTT assay of wild-type (WT) and *POMGnT1*^{-/-} myoblasts after infection with retrovirus vectors. Impaired proliferation of *POMGnT1*^{-/-} myoblasts was not recovered by retrovirus-mediated expression of *POMGnT1*. Representative data of three independent experiments are shown.

3.2. Null mutation in *POMGnT1* reduces proliferative activity of muscle satellite cells

POMGnT1^{-/-} myoblasts proliferate poorly *in vitro*. This observation suggested that the proliferation of myoblasts is stimulated by growth signals via laminin- α -DG interaction.

However, retrovirus vector-mediated gene transfer of the *POMGnT1* gene, which successfully restored O-mannosyl glycosylation of α -DG, did not restore the proliferation activity of the *POMGnT1*^{-/-} myoblasts. DMD myoblasts proliferate poorly and quickly reach senescence. The impaired proliferation activity has been ascribed to repeated activation of

satellite cells due to repetitive cycles of muscle degeneration and regeneration (Blau et al., 1983). In contrast, *POMGnT1*^{-/-} muscle lacks signs of active regeneration. Therefore, the reduced proliferation activity of *POMGnT1*^{-/-} mouse myoblasts is not likely due to excessive cell division of satellite cells. Rather, it is likely that α -DG-laminin interaction in the niche, i.e. beneath the basal lamina of skeletal muscle myofibers, is important for maintenance of proliferative activity of satellite cells. However, the possibility that *POMGnT1*-deficiency causes aberrant glycosylation of molecules other than α -DG should be also tested.

Our results also suggested that the lack of α -DG-laminin interaction resulted in reduced numbers of muscle fibers (hypoplasia). Importantly, we found that myofibers of older *POMGnT1*^{-/-} mice tend to be hypertrophied (Supplementary Fig. 2). *POMGnT1*^{-/-} muscle might compensate the muscle power by hypertrophy of the myofibers. This is consistent with our observation that *POMGnT1*^{-/-} muscle increases its mass in an overload model (unpublished data). Importantly, recent studies suggest that this process is satellite cell-independent (Sandri M., 2008).

Recently, Liu et al. showed that over-expression of integrin α 7 β 1 in C2C12 myoblasts promoted proliferation of the cells (Liu et al., 2008). Importantly, however, we did not observe up-regulation of integrin α 7 β 1 expression in *POMGnT1*^{-/-} satellite cells. These observations suggest that dystroglycans and integrins have distinct roles in the regulation of muscle satellite cells.

In summary, we generated *POMGnT1*-null mice. The mice showed low serum creatine kinase levels and minimal signs of muscle degeneration and regeneration. Nonetheless, *POMGnT1*^{-/-} muscle showed the reduction in the size and the number of myofibers. Furthermore, repeated injection of cardiotoxin showed impaired muscle regeneration in *POMGnT1*^{-/-} mice. *POMGnT1*^{-/-} myoblasts proliferated poorly *in vitro*. Over-expression of protein restored glycosylation of α -DG, but did not improve the proliferation of *POMGnT1*^{-/-} myoblasts at all. Collectively, our results suggest that *POMGnT1* enzymatic activity is important for maintenance of the proliferative activity of satellite cells *in vivo*.

4. Experimental procedures

4.1. Generation of *POMGnT1*^{-/-} mice

The targeting strategy in ES cells is depicted in Fig. 1. Genomic DNA (8.6 kb) covering almost the entire *POMGnT1* gene was isolated from 129/SvJ mice by using two specific primers: m1F2 primer, 5'-gat tcc tga agt cat gga ctg gc-3' and m1B5, 5'-tct aaa ggt ctc tgt gtg agt ctg tca g-3'. The PCR product was then cloned into a TOPO TA cloning vector (Invitrogen, Carlsbad, CA) and sequenced (AB053221). To construct the targeting vector, a 630-bp RsrII-Hind III fragment, containing exon18 was replaced with a *neo* expression cassette (Stratagene) (Fig. 1). Electroporation and screening of ES cells (129Svev origin) were performed by Ingenious Targeting Laboratory, Inc. (Stony Brook, NY). Homologous recombination in ES cells was confirmed by Southern blotting. Two independent positive ES clones were injected into C57BL/6 blastocysts,

which gave rise to offspring carrying the mutated allele. Genotyping of the mice was done by PCR. One primer set is designed to amplify exon 18: F2, 5'-cag cag ttt cct tcc ttc taa ccc-3' and B4, 5'-att tgg tct ggt ccc ttg gct c-3' (278 bp). *Neo* primers were used to amplify the *neo* resistance gene, and thereby detect the mutant allele: neo-F, 5'-agg cta ttc ggc tat gac tgg g-3', and neo-R, 5'-tac ttt ctc ggc agg agc aag gtg-3' (288 bp). Dystrophin-deficient *mdx* mice of C57BL/6 genetic background were provided by T. Sasaoka at the National Institute for Basic Biology, Japan. The Experimental Animal Care and Use Committee of the National Institute of Neuroscience approved all experimental protocols.

4.2. *POMGnT1* enzymatic activity

Brains were obtained from 8-week-old mice and homogenized with nine volumes (weight/volume) of 10 mM Tris-HCl, pH 7.4, 1 mM EDTA, and 250 mM sucrose. After centrifugation at 900g for 10 min, the supernatant was subjected to ultracentrifugation at 100,000g for 1 h. The precipitates were used as the microsomal membrane fraction. The protein concentration was determined by BCA assay (Pierce, Rockford, IL). The enzymatic activity assay measured the amount of [³H]GlcNAc transferred to a mannosyl peptide (Akasaka-Manya et al., 2004). Briefly, a reaction mixture containing 140 mM Mes buffer (pH 7.0), 1 mM UDP-[³H]GlcNAc (80,000 dpm/nmol, PerkinElmer, Inc., Wellesley, MA), 2 mM mannosyl peptide (Ac-Ala-Ala-Pro-Thr-(Man)-Pro-Val-Ala-Ala-Pro-NH₂), 10 mM MnCl₂, 2% Triton X-100, 5 mM AMP, 200 mM GlcNAc, 10% glycerol, and 100 μ g of microsomal membrane fraction was incubated at 37 °C for 1 h. After boiling for 3 min, the mixture was analyzed by reverse phase HPLC using a Wakopak 5C18-200 column (4.6 \times 250 mm, Wako Pure Chemical Industries, Osaka, Japan). The gradient solvents were aqueous 0.1% trifluoroacetic acid (solvent A) and acetonitrile containing 0.1% trifluoroacetic acid (solvent B). The mobile phase consisted of 100% A for 10 min and then a linear gradient to 75% A:25% B over 25 min. Peptide separation was monitored at 214 nm, and the radioactivity of each fraction (1 ml) was measured using a liquid scintillation counter.

4.3. Antibodies

All antibodies used in Western blotting, immunohistochemistry, and FACS are listed in Supplementary Table 1.

4.4. Histology and immunohistochemical analysis

Muscle cryosections (6–10 μ m) were stained with hematoxylin and eosin (H&E), or treated with 0.1% Triton X-100, blocked with 5% goat serum/1% BSA in PBS, then incubated with primary antibodies (Supplementary Table 1) at 4 °C overnight. After washing with PBS, specimens were incubated with a secondary antibody labeled with Alexa Fluor 488 or Alexa Fluor 568 (1:200–400 dilution; Molecular Probes) at RT for 1 h, counterstained with TOTO-3 (1:5000; Molecular Probes), and then mounted in Vectashield (Vector). The images were recorded using a confocal laser scanning microscope system TCSSP™ (Leica). For fiber size measurement, cross-sections of muscle were stained with anti-laminin α 2

antibody and recorded and quantified by a digital microscope, BIOREVO (<http://www.biorevo.jp>; KEYENCE, Osaka, Japan).

4.5. Western blotting

Western blotting was performed as previously described (Hosaka et al., 2002). In brief, 20 µg of muscle proteins were separated on 7.5% SDS-PAGE gels and transferred to a PVDF membrane (Millipore, Bedford, MA). After incubation with primary antibodies (Supplementary Table 1), the membranes were incubated in HRP-labeled secondary antibodies (1:5000 dilution) (Amersham Biosciences, UK). The signals were detected by using an ECL plus Western Blotting Detection System (GE Healthcare, Buckinghamshire, UK).

4.6. Laminin blot overlay assay

An overlay assay was performed as described by Moore et al. (2002). In brief, WGA-enriched homogenates were prepared from wild-type and *POMGnT1*^{-/-} brains, separated on SDS-PAGE gels, blotted onto a PDVF membrane, and incubated with mouse EHS laminin (Trevigen, Gaithersburg, MD, USA). Bound laminin was probed with anti-laminin antibody (Sigma, St. Louis, MO) and ECL system (GE Healthcare, Buckinghamshire, UK).

4.7. Single fiber preparation and culture

Single fibers were prepared from extensor digitorum longus (EDL) and soleus muscles of wild-type and *POMGnT1*^{-/-} mice as described by Rosenblatt et al. (1995). Each fiber was plated onto Matrigel (BD Biosciences, Bedford, MA)-coated 24-well plates and cultured in growth medium for 3 days. Then, the number of cells around the parental fiber was counted.

4.8. Isolation of satellite cells, proliferation assay, and fusion index

Satellite cells were prepared from wild-type and *POMGnT1*^{-/-} mice by FACS as previously described (Fukada et al., 2007). Sorted cells were plated on Matrigel-coated 24-well-plates at a density of 1×10^4 cells/well in a growth medium, DMEM (High glucose; Wako, Osaka), supplemented with 20% fetal bovine serum (Equitech-bio, Inc., Kerville, TX), human recombinant bFGF (2.5 ng/ml) (Invitrogen), recombinant mouse HGF (25 ng/ml) (R&D Systems, Minneapolis, MN), and heparin (5 µg/ml) (Sigma). For the MTT assay, 100 µl of 0.5% MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Dojindo, Kumamoto, Japan) was added to the culture at each time point, and after 4 h incubation, the cells were collected in 1 ml of acid isopropanol solution. OD₅₉₀ was measured and plotted. After reaching 70% confluency, the cells were induced to differentiate into myotubes by low-serum medium (5% horse serum/DMEM), and 18 h later, the cells were fixed, stained with anti-sarcomeric α -actinin antibody and DAPI (nuclei). Fusion index was calculated as (the numbers of nuclei in the myotubes/total nuclei) \times 100%.

4.9. Production of retrovirus vectors

pMXs-IG (Kitamura et al., 2003) was kindly provided by T.Kitamura at Tokyo University. Human POMGnT1 cDNA, which has an Xpress epitope and a His-tag at the N-terminal (Akasaka-Manya et al., 2004), was cloned into the multi-cloning site upstream of IRES-GFP of the vector. Vector particles were produced by transfection of the vector plasmid into PLAT-E packaging cells (Kitamura et al., 2003). Proliferating satellite cells (myoblasts) were incubated with the viral vectors overnight and 4 days later, successfully transduced GFP-positive cells were collected by FACS, and the proliferation rate was evaluated by MTT assay.

4.10. Electron microscopy

Mice were perfused transcardially with a solution of 2% paraformaldehyde and 2.5% glutaraldehyde in PBS under deep pentobarbital anesthesia. The anterior tibial muscles were excised, embedded in 3% agarose, and sections (70 µm in thickness) were prepared on a Vibratome. Sections were fixed in OsO₄, ehydrated, and embedded in Cartepoxy resin. Ultrathin sections were prepared, stained with lead citrate and uranyl acetate, and observed under a Hitachi H-7000 transmission electron microscope.

4.11. Measurement of serum creatine kinase (CK)

Blood samples were obtained from the tail vein or directly from the heart at sacrifice. Serum CK level was measured by colorimetric assay using an FDC3500 clinical biochemistry autoanalyzer (FujiFilm Medical Co., Tokyo, Japan).

4.12. Cardiotoxin (CTX) injection

To induce muscle regeneration, CTX (10 µmol/L in saline; Sigma, St. Louis, MO) was injected into the tibialis anterior (TA) muscles three times at indicated intervals. The muscle cross-sections were stained with Oil red O (Muto Pure Chemicals Co., Ltd., Tokyo, Japan) to detect lipid droplets, or with Sirius red F3B (Sigma Chemical Co., St. Louis, MO) in saturated picric acid to stain collagen fibers.

A Renaissance for Antisense Oligonucleotide Drugs in Neurology

Exon Skipping Breaks New Ground

Toshifumi Yokota, PhD; Shin'ichi Takeda, MD, PhD; Qi-Long Lu, MD, PhD;
Terence A. Partridge, PhD; Akinori Nakamura, MD, PhD; Eric P. Hoffman, PhD

Antisense oligonucleotides are short nucleic acid sequences designed for use as small-molecule drugs. They recognize and bind to specific messenger RNA (mRNA) or pre-mRNA sequences to create small double-stranded regions of the target mRNA that alter mRNA splicing patterns or inhibit protein translation. Antisense approaches have been actively pursued as a form of molecular medicine for more than 20 years, but only one has been translated to a marketed drug (intraocular human immunodeficiency virus treatment). Two recent advances foreshadow a change in clinical applications of antisense strategies. First is the development of synthetic DNA analogues that show outstanding stability and sequence specificity yet little or no binding to modulator proteins. Second is the publication of impressive preclinical and clinical data using antisense in an exon-skipping strategy to increase dystrophin production in Duchenne muscular dystrophy. As long-standing barriers are successfully circumvented, attention turns toward scale-up of production, long-term toxicity studies, and the challenges to traditional drug regulatory attitudes presented by tightly targeted sequence-specific drugs.

Arch Neurol. 2009;66(1):32-38

With the advent of recombinant DNA in the 1970s, it was soon realized that bacteria possess a form of regulatory machinery where small RNA transcripts can bind (hybridize) to other target RNAs and inhibit the translation of these targets.¹ These antisense RNAs were subsequently recognized as natural translational regulation mechanisms in plants and higher organisms.² More recently, a specialized form of antisense transcript was found to be a cellular defense mechanism against invading messenger RNAs (mRNAs) (viruses), and this has been harnessed as a popular method to "knock down" specific mRNA transcripts in cultured cell models (short interfering RNAs).³

Attention soon shifted toward development of antisense molecules as a form

of small-molecule drug (antisense oligonucleotide [AO]). The approach was intuitive: one needs simply to chemically synthesize short pieces of DNA of about 20 bases, where a specific complementary sequence is designed to hybridize with a desired target mRNA. Such designer AO drugs should show very high specificity and selectivity for binding only the desired target RNA sequence of nucleotides that is predicted by base pairing. Beginning in the mid-1980s, this approach was put to the test in model systems and was shown to work quite well in shutting down the production of the target (undesired) protein.⁴ Isis Pharmaceuticals, Inc, Carlsbad, California, a company focused on clinical applications of AOs, was incorporated in 1989. Additional companies focusing on AO approaches soon followed.

Despite early promise, uses of AOs as small-molecule drugs have been painfully slow to enter the market and standard of care. Indeed, only a single AO drug has been approved by the Food and Drug

Figure 1. Comparison of chemistries used for the exon-skipping approach. Examples of artificially developed antisense oligomers such as 2'-O-methylated antisense oligonucleotides (2'-O-MeAO) (phosphorothioate), locked nucleic acid (LNA), phosphorodiamidate morpholino oligomers (PMOs), and peptide-tagged PMOs (PPMOs) are shown for comparison with DNA and RNA.

Administration (FDA), fomivirsen sodium (Vitravene; Isis Pharmaceuticals, Inc) delivered by intravitreal injection to inhibit cytomegalovirus retinitis in AIDS. Vitravene was approved in 1998 and there have been no subsequent successful approvals in the ensuing 10 years.

What has slowed the progress of AO drugs into the clinical arena, and why may this be changing?

There have been 2 major hurdles: off-target toxic effects and potency or delivery. Regarding toxic effects, most organisms do not take kindly to covert infiltration by foreign DNA or RNA. Indeed, all species have quite effective mechanisms to destroy foreign DNA and RNA as they are more likely than not to be viruses or other undesirable organisms. In addition, many of the clinical trials testing AO drugs have seen evidence of activation of the complement cascade, and this has been a key concern of the FDA. Delivery has also been a consistent problem. Because the target RNAs are always intracellular, it is imperative for the AO drug to achieve intracellular concentrations sufficient to enable it to bind and modulate the target RNA to a significant extent. The fact that AOs typically do not easily cross the lipid bilayers that bound the

cell so as to achieve sufficient intracellular potency via systemic (intravenous) delivery has been problematic.

Recent developments are achieving success in overcoming both hurdles. Analogues of nucleic acid have been designed and synthesized in which the ribose backbone of RNA and DNA is replaced with different chemistries (**Figure 1**). Two are particularly promising: one uses a morpholino backbone (phosphorodiamidate morpholino oligomer [PMO]; AVI BioPharma, Portland, Oregon), and the second uses a locked nucleic acid backbone (Enzon Pharmaceuticals, Inc, Bridgewater, New Jersey). These new backbones are designed to maintain the molecular distance between bases (G, A, T/U, and C), enabling highly sequence-specific base pairing to the target RNA that is stronger in the case of PMO and locked nucleic acid drugs than DNA or RNA AOs. Equally important, these backbones are so dissimilar from the DNA and RNA ribose phosphodiester backbone that they are not recognized by most or any DNA and RNA binding proteins or degrading enzymes, thereby enhancing their stability and avoiding many or all off-target toxic effects.

The second major barrier has been achieving sufficient intracellular concentrations (delivery). One successful approach is to take advantage of preexisting holes in the plasma membrane of the target cell. Infecting viruses breach the cell membrane during the process of infection and appear to bring along AO drugs in the process. As such, AOs have been quite successful in blocking downstream viral replication within cells, and PMO drugs are showing impressive promise as antiviral antidotes.⁵ Another preexisting hole is found in muscle cells lacking dystrophin (Duchenne muscular dystrophy [DMD]).⁶ The unstable plasma membrane of myofibers appears to allow the AO to leak into the cell.⁷ An additional approach is to modify the AO drugs with cell delivery moieties, chemical adducts that penetrate the cell membrane. One example is the addition of arginine-rich peptides to one end of the AO drug (peptide-tagged PMO) (Figure 1).

From these advances has sprung a resurgence of interest in AO drugs for treatment of genetic disease, cancer, and infectious disease. The purpose of most applications is to knock down a target RNA so that it makes less of the deleterious protein product (eg, tumor growth factor β or hypoxia-inducible factor 1α in cancer cells, viral mRNAs, or dominant gain-of-function toxic proteins in inherited neurological disease). However, the disorder that may be most advanced in such applications is DMD. Here the AOs are used for a quite different objective than for previous applications; explicitly, AOs in DMD are designed to restore function to the target mRNA and protein rather than block it. The remainder of this review focuses on this application.

RATIONALE AND PROOF OF PRINCIPLE OF EXON-SKIPPING THERAPY

The principle of exon-skipping therapy for dystrophinopathies was initially demonstrated by Duncley et al⁸ in cultured mouse muscle cells in vitro. The rationale is as follows. Duchenne muscular dystrophy is caused by mutations of the 79-exon gene (commonly deletions of ≥ 1 exon). Within the myofiber, the remainder of the gene will be transcribed and spliced together. However, if the triplet codon reading frame of the mRNA is not preserved, the resulting frame shift will lead to the failure of dystrophin protein production. Becker muscular dystrophy (BMD) is a clinically milder and more variable disease in which mutations of the dystrophin gene are commonly such as to preserve the translational open reading frame; thus, after splicing together, the remainder of the gene retains some ability to synthesize the dystrophin protein. The goal of exon-skipping therapies is to force the dysfunctional mRNA with out-of-frame mutations in a patient with DMD to skip (exclude) some additional exons. The loss of additional material directed by AO drugs restores the reading frame, changing a Duchenne out-of-frame transcript to a Becker in-frame transcript. Fortunately, most mutations in the dystrophin gene occur in parts that do not code for functionally essential regions of the protein.

This AO-mediated exon-skipping method has been developed and extensively tested on the dystrophic *mdx* mouse model of DMD. The *mdx* mouse harbors a non-

sense mutation in exon 23 that prevents translation beyond this point in the transcript. Both local intramuscular injection and systemic delivery of a single AO targeted against exon 23 in the primary transcript excludes this exon from the mRNA, leaving an in-frame transcript that generates dystrophin expression and produces a degree of functional recovery. Intramuscular and systemic injections of AOs for exon splicing of a dog model of DMD have also been demonstrated with a novel cocktail AO strategy (T.Y., S.T., Q.-L.L., T.A.P., A.N., E.P.H., and Masanori Kobayashi, DVM, unpublished data, 2006-2008). The principle is similarly illustrated in humans; van Deutekom et al⁹ reported single-site intramuscular injections of 2'-O-methyl AO chemistry in 4 boys with DMD, showing evidence of de novo dystrophin production at the injection site.

These data demonstrate that the key hurdles of achieving intracellular delivery and avoiding toxic effects can be cleared. A similar strategy is being explored in other diseases such as myotonia, human immunodeficiency virus, and spinal muscular atrophy.¹⁰⁻¹²

HURDLES IN BRINGING EXON SKIPPING TO STANDARD OF CARE

Exon skipping using AO drugs has rapidly emerged as the frontline therapeutic approach for DMD. How soon can we expect exon skipping to reach the neuromuscular clinic and standard of care? This approach is breaking new ground and raising challenges not encountered previously in drug development. Different patients have different mutations, and many AO sequences will need to be designed, tested, and FDA approved. Also, current genotype and phenotype data suggest that there may be good in-frame deletions and not-so-good in-frame deletions; simply restoring the reading frame may not be synonymous with restoring dystrophin protein function. The optimization of dystrophin function will likely require deletions of multiple exons, and this will require mixtures of different AOs—new territory for drug development and the FDA. The approach will require regular injections of large amounts of AO drug; what are the long-term toxic effects? Moreover, are the standard toxicity tests appropriate for sequence-specific drugs? Each of these hurdles is discussed briefly in the remainder of this review.

CERTAIN EXON DELETIONS MAY RETAIN MORE DYSTROPHIN FUNCTION THAN OTHERS

The molecular diagnostics of DMD and BMD frequently refer to the reading frame rule, where out-of-frame deletions are given a DMD diagnosis and in-frame deletions are given a BMD diagnosis. However, as many as 30% of patients with BMD do not adhere to this rule.¹³ A thorough understanding of reading frames is critical for appropriate design of exon-skipping therapies, both so that the best AO can be given to the patient and so that an optimally functional dystrophin protein is produced as a result of the expected exon skipping. Currently, the best information from which to predict the capabilities of partially deleted dystrophins to rescue the DMD phenotype comes from analysis of the thousands of geno-

Figure 2. Clinical phenotypes associated with specific start (A) and end (B) sites for in-frame deletions. Percentages of patients with Duchenne muscular dystrophy (DMD) out of patients with DMD or Becker muscular dystrophy with specific start and end exons are shown. Combined muscular dystrophy databases of 14 countries (from Argentina, Belgium, Brazil, Bulgaria, Canada, China, Denmark, France, India, Italy, Japan, The Netherlands, the United Kingdom, and the United States) at Leiden University (<http://www.dmd.nl>), where diagnoses were performed using multiplex ligation-dependent probe amplification/multiplex amplification and probe hybridization, Southern blotting, or polymerase chain reaction primer sets that allow deletion boundaries to be assigned accurately to a specific exon, are used (deletion start sites: n=288 for exon 45, n=23 for exon 47, n=9 for exon 48, n=12 for exon 49, and n=10 for exon 50; deletion end sites: n=11 for exon 46, n=115 for exon 47, n=95 for exon 48, n=51 for exon 49, n=53 for exon 51, n=40 for exon 53, and n=21 for exon 55).

type and phenotype correlations in patients with DMD and BMD that have been published in the literature and on the Internet. We examined all in-frame deletions and determined the proportion of observed cases that showed mild or severe phenotypes. This was gleaned from combined muscular dystrophy databases of 14 countries (from Argentina, Belgium, Brazil, Bulgaria, Canada, China, Denmark, France, India, Italy, Japan, The Netherlands, the United Kingdom, and the United States) at Leiden University (<http://www.dmd.nl>), excluding diagnoses that did not allow deletion boundaries to be assigned accurately to a specific exon.¹⁴ Of all observed in-frame deletion patterns on genomic DNA in the central rod domain hotspot region (exons 42-57; 28 distinct patterns), 57% (16 of 28 patterns) were associated with DMD rather than BMD. This analysis showed that there are considerable discrepancies between population-based ratios and pattern-based proportions of severe DMD vs mild BMD phenotypes, and interestingly, the ratio of DMD to BMD remarkably varies between specific deletion patterns. For example, in-frame deletions starting or ending around exon 50 or 51 that encode the hinge region were most commonly associated with severe phenotypes (Figure 2) (eg, deletions at exons 47-51, 48-51, and 49-53 are all reported to be associated with a severe DMD phenotype rather than BMD).^{15,16}

Two questions arise. First, why do specific patterns of in-frame mutations tend to result in a severe DMD phenotype in contradiction to the reading frame rule? Second, why do different individuals with the same exonic deletion pattern exhibit such different clinical phenotypes? Likely contributory factors include the following: the effect of the specific deletion breakpoints on mRNA splicing efficiency and/or patterns; translation or transcription efficiency after genome rearrangement; and stability or function of the truncated protein structure. The mechanisms controlling accurate splicing of the 79-exon, 2.4 million-base pair dystrophin gene are clearly

complex. Introns of the dystrophin gene are highly variable in size, and it is likely that exonic splicing does not take place in an ordered 5' to 3' sequence. A complication in interpreting genotype and phenotype correlations is that the deletion in genomic DNA does not always correspond to the material missing from the resulting mRNA. We and others have shown that even in the absence of AOs, a patient may produce 1 or more transcripts that skip additional exons present in the genomic DNA, in effect performing their own private exon skipping.¹⁵ Disruption of splice site information (such as an intervening sequence) in some patients with in-frame gene deletions may cause skipping of additional exons at mRNA splicing, thus leading to out-of-frame transcripts from an in-frame genomic DNA deletion as Kesari et al¹³ have recently described. As Menhart¹⁷ has pointed out, it is also likely that quasi-dystrophin variants in the rod domain may show different stability or function because of different types of derangement of spectrinlike repeat domains. Not enough is known about dystrophin structure and function, and the relative importance of the protein sequence within the rod domain remains entirely a matter of speculation. Historically, lack of dystrophin expression has been used as the key criterion for DMD diagnosis. This together with the presence of the DMD clinical picture with such in-frame mutations argues that other confounding variables such as imprecisely defined mutation or aberrant splicing may explain these "exceptions to the reading frame rule." Thus, it is anticipated that most or all patients with mutations in the central rod domain would benefit from the production of truncated dystrophin.

PARALLELING AO TRIALS: TESTING NEW EXONS AND MIXTURES

Clinical proof-of-concept trials testing limited intramuscular injection with a 2'-O-methyl AO against exon 51

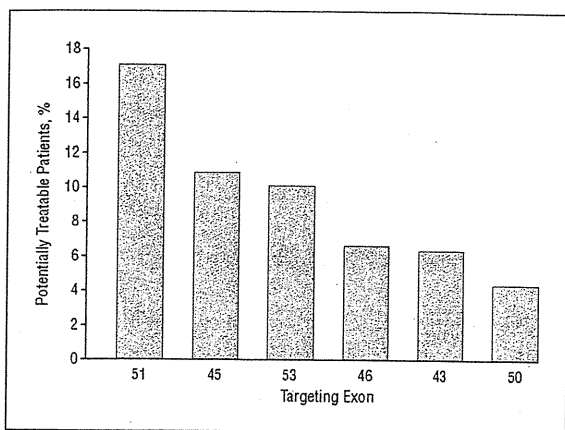

Figure 3. Targets of exon skipping and population of potentially treatable patients. Percentage of patients with the dystrophin deletion who are potentially treatable by targeting specific exons for Duchenne muscular dystrophy. For example, 17% of patients with Duchenne muscular dystrophy who have the dystrophin deletion can be potentially treated by targeting exon 51 using antisense oligonucleotides.

have been published,⁹ and similar studies with PMO chemistry are under way in the United Kingdom. Given the many questions concerning the sequence specificity of toxic effects and the large number of AO sequences that will need to be developed as drugs to treat most patients with DMD, it is critical to parallel studies on many more AOs for DMD (**Figure 3**).

It should be noted that about 30% of patients with DMD have nondeletion mutations (duplication, nonsense mutations, small rearrangement, or splice site mutations). Most mutations are theoretically amenable to exon skipping; however, there are no hot spots for point mutations, so relatively few patients would be treatable with each targeted exon by comparison with deletion mutations. Moreover, if skipped to remove a nonsense mutation, the exons that are candidates to restore the reading frame in patients with deletions (eg, exons 43, 45, 46, 50, 51, and 53) will require additional deletion of at least 1 further exon to restore the reading frame because these are frame-shifting exons. Thus, only 35% of nonsense mutations are potentially treatable by single-exon targeting, but the combined data of the Leiden DMD mutation database imply that more than 90% could be responsive to multiskipping.¹⁴

Development of exonic cocktails (mixtures) could resolve a number of problems, including optimization of dystrophin function and covering relatively high proportions of patients with DMD with a single mixture. The mixture approach has clear advantages and disadvantages. As an example, an 11-exon AO cocktail skipping exons 45 through 55 is predicted to result in a particularly mild BMD phenotype (94% of reported patients).¹⁴ Encouragingly, this large deletion is regularly associated with clinically milder phenotypes than any of the smaller in-frame deletions within the same range of exons 45 to 55.¹⁸ A second advantage is that the cocktail could conceivably be approved as a single drug for most patients with DMD who have dystrophin deletions, independent of their precise deletion, eg, an 11-exon AO cocktail targeting exons 45 through 55 is potentially ap-

plicable to more than 60% of patients with a dystrophin deletion (**Figure 4**).^{18,19} In total, more than 90% of patients with DMD could potentially be treated by multiskipping, whereas single-exon skipping could treat around half of the patients with dystrophin deletions and point mutations. Systemic studies in the large dog model of DMD have been done using a 3-exon PMO cocktail, and this has clearly been shown to be efficacious by multiple clinical, imaging, histological, and biochemical or molecular end points (T.Y., S.T., Q.-L.L., T.A.P., A.N., E.P.H., and Masanori Kobayashi, DVM, unpublished data, 2006-2008).

A disadvantage of the cocktail approach is the addition of novel hurdles for FDA or regulatory approval. Current FDA regulations require each component of a drug mixture to undergo toxicological and clinical testing and then require the mixture to similarly undergo toxicological and clinical testing. In the context of an ideal 11-exon AO cocktail, the regulatory barriers become truly intimidating. In addition, the 11-exon cocktail PMO approach would lead to delivery of some AOs that may not have a target in a specific patient (eg, the patient already has a deletion of ≥ 1 exon in the AO mix). Thus, some parts of the mixture will have no possible potential molecular or clinical benefit to individual patients. This would again be uncharted territory for the FDA. While clinical development of the 11-exon mixture is likely ambitious at present, it will be important to initiate toxicological and clinical trials of exon mixtures for subsets of patients who cannot be treated with a single AO. Also, for future trials on multiskipping such as with exons 45 through 55, we should have as many AOs in hand as possible because they can be used as part of multiskipping AOs.

PERSONALIZED MEDICINE AND THE FDA: ARE EXISTING GUIDELINES APPROPRIATE?

Personalized medicine has many definitions, but most share the concept of optimizing a treatment for a particular patient. Designing and using AO drugs targeted for a patient's specific gene mutation would seem to fit well within this rubric. As such, the promising AO exon-skipping approach may bring neuromuscular disease to the frontline in development of drugs for personalized medicine. It is important to examine the existing FDA guidelines for drug development and reinterpret these guidelines in the context of AO and DMD. For example, the drug development pipeline includes phase I studies of the drug in healthy volunteers. However, successful on-target exon skipping of the dystrophin gene in healthy volunteers would give them DMD, a clear adverse effect that is entirely irrelevant to toxic effects in the target patient population (boys with DMD). Toxicity tests are currently done in animal models (typically 2 species), but one of the major concerns regarding toxic effects of AO drugs is binding to off-target RNAs. For example, if an AO drug designed for exon skipping of the dystrophin mRNA also binds to the closely related utrophin mRNA, then exon skipping of utrophin might occur and could result in off-target adverse effects. The utrophin sequence of mice or rats is different from the utrophin sequence of humans, so the standard rodent toxicity tests

Figure 4. Mechanism of multiexon skipping of exons 45 through 55 to rescue 60% of patients with Duchenne muscular dystrophy with dystrophin deletions. A, More than 60% of deletion mutations of the dystrophin gene occur within the hot-spot range of exons 45 through 55 (exon 45 is deleted in this schematic [del]) in Duchenne muscular dystrophy muscles. The messenger RNA (mRNA) of remaining exons is spliced together but the reading frame is disrupted, resulting in failure of the production of functional dystrophin protein. CK indicates creatine kinase; Ca^{2+} , calcium ions. B, An antisense oligonucleotide (AO) cocktail targeting exons 45 through 55 likely enters the Duchenne muscular dystrophy muscle through its leaky membranes, then binds to the dystrophin mRNA in a sequence-specific manner. The AOs block the splicing machinery and prevent inclusion of all exons between exons 45 and 55. Skipping these exons restores the reading frame of mRNA, allowing production of quasi-dystrophin containing exons 1 through 44 and exons 56 through 79, which is not normal but likely retains considerable function as evidenced by patients with clinically milder Becker muscular dystrophy with identical partial dystrophin.

may not accurately assess off-target toxic effects of AOs for human use.

Perhaps the largest challenge facing implementation of exon-skipping therapy for DMD is in developing new approaches to toxicity testing and clinical trial regulatory procedures that are relevant and appropriate for sequence-specific drugs. The pharmaceutical industry often quotes a price tag of \$500 million to bring any new drug to the market. Given the discussion earlier, implementation of AO drugs in DMD will require many exon-specific drugs. If the \$500 million is assessed for each individual AO sequence, then both time and money become insuperable barriers to helping the existing generation of boys with DMD. The silver lining in this cloud is the lack of any detectable toxic effects with PMO AO drugs to date. If multiple AOs all show a lack of long-term toxic effects, then there is hope that specific AO drugs could be approved with more limited toxicological and phase 1 testing.

A practical resolution of this problem is to consider each component of the potential toxic effects of these highly targeted drugs individually. Tests of the generic toxic effects of morpholinos at the doses at which they

are likely to be functionally effective could be conducted quite straightforwardly with either a scrambled or arbitrary sequence of a particular molecular weight. It is the notion of individual sequence-specific toxic effects that raises problems. The argument that any specific sequence may have off-target effects (eg, binding to utrophin transcripts) cannot be properly tested in other species because they may have different potential off-target sequences as compared with those in humans. This carries the dire implication that a lack of sequence-specific toxic effects in a test species can provide no assurance, indeed no information at all, as to the sequence's safety in humans. Tests in healthy human volunteers are also problematic. Ethical issues arise from the possible generation of a pathogenic frameshift in healthy muscle by successful suppression of the targeted exon. Moreover, the lack of innate pathological abnormalities in healthy human muscle would stifle access of the AO to its intended intramuscular target while at the same time providing a different spectrum of potential off-target molecules (eg, utrophin transcripts). A further complication arises from the individualistic nature of the entire rationale, for it precludes the possibil-

ity of learning from experience; the probability that any given sequence may be toxic is independent of the number of safe experiences with other sequences. In effect, for safety, we can test for sequence-specific toxic effects only in human volunteers with DMD by progressive dose escalation. Only in this way would the reagents have access to their intended targets as well as any unintended targets in a physiological context that is inappropriately modeled both in other species and in healthy human volunteers.

Recombinant adeno-associated virus (rAAV)-mediated gene transfer is an attractive approach to the treatment of Duchenne muscular dystrophy (DMD). We investigated the muscle transduction profiles and immune responses associated with the administration of rAAV2 and rAAV8 in normal and canine X-linked muscular dystrophy in Japan (CXMD) dogs. rAAV2 or rAAV8 encoding the *lacZ* gene was injected into the skeletal muscles of normal dogs. Two weeks after the injection, we detected a larger number of β -galactosidase-positive fibers in rAAV8-transduced canine skeletal muscle than in rAAV2-transduced muscle. Although immunohistochemical analysis using anti-CD4 and anti-CD8 antibodies revealed less T-cell response to rAAV8 than to rAAV2, β -galactosidase expression in rAAV8-injected muscle lasted for <4 weeks with intramuscular transduction. Canine bone marrow-derived dendritic cells (DCs) were activated by both rAAV2 and rAAV8, implying that innate immunity might be involved in both cases. Intravenous administration of rAAV8-*lacZ* into the hind limb in normal dogs and rAAV8-*microdystrophin* into the hind limb in CXMD dogs resulted in improved transgene expression in the skeletal muscles lasting over a period of 8 weeks, but with a declining trend. The limb perfusion transduction protocol with adequate immune modulation would further enhance the rAAV8-mediated transduction strategy and lead to therapeutic benefits in DMD gene therapy.

INTRODUCTION

Duchenne muscular dystrophy (DMD) is an inherited disorder causing progressive deterioration of skeletal and cardiac muscles because of mutations in the dystrophin gene. No effective treatment has been established despite the development of various

novel therapeutic strategies including pharmacologic and gene therapies. Dystrophin-deficient *mdx* mice and dystrophin-utrophin double-knockout mice are the animal models most widely used to evaluate therapeutic efficacy, although the symptoms of *mdx* mice are not comparable to those of human DMD patients. Dystrophin-deficient canine X-linked muscular dystrophy was found in a golden retriever,^{1,2} and we have established a Beagle-based model of canine X-linked muscular dystrophy in Japan (CXMD) dogs.³ The clinical and pathological characteristics of the dystrophic dogs are more similar to those of DMD patients than murine models.³

The recombinant adeno-associated virus (rAAV) can be used for delivering genes to muscle fibers. Several serotypes of rAAV exhibit a tropism for striated muscles.^{4,5} Intramuscular or intravenous administration of rAAV carrying the microdystrophin gene was reported to restore specific muscle force and extend the lifespan in dystrophic mice.^{6,7} In contrast to the success of transgene delivery in mice, rAAV2 or rAAV6 delivery to canine striated muscles without immunosuppression resulted in insufficient transgene expression, and rAAV evoked strong immune responses.^{8,9} An assay of interferon- γ released from murine and canine splenocytes suggested that the immune responses against rAAV and transgene products in mice and in dogs are dissimilar.⁸ Uptake of rAAV2 by human dendritic cells (DCs) and T-cell activation in response to the AAV2 capsid have been reported,¹⁰ indicating that DCs play key roles in the immune response against rAAV-mediated transduction. On the other hand, other serotypes, including rAAV8, that are capable of whole-body skeletal muscle expression after intravenous administration,^{4,5} induce less T-cell activation.¹¹ We hypothesized that the level of activation of canine DCs by rAAV8 might be lower than that achieved by rAAV2. However, the transduction profile and immune response in the rAAV8-injected dog skeletal muscle have not been elucidated.

In this study, we chose to use intramuscular injections under ultrasonographic guidance so as to minimize the inflammatory reaction caused by incisional intramuscular injection.⁸ In

addition, intravascular delivery was performed as a form of limb perfusion, in an attempt to bypass the immune activation of DCs in the injected muscle.¹² We investigated the transgene expression and host immune response to two distinct serotypes of rAAV in normal and dystrophic dogs after direct intramuscular injection and after limb perfusion.

RESULTS

Extensive expression of β -galactosidase in rAAV8-transduced muscles in wild-type dogs

We administered nonincisional intramuscular injections under ultrasonographic guidance so as to minimize injury. With incisional injection, the ordinary method of intramuscular viral administration in dogs,⁸ the skin is opened to identify the individual muscles. This may enhance the immune reaction by recruiting inflammatory cells for wound healing. After nonincisional injection of rAAV2-*lacZ*, faint β -galactosidase (β -gal) expression was detected, whereas lymphocyte infiltration still occurred (Supplementary Figure S1). To investigate the transduction efficiency of rAAV8 in canine skeletal muscle, normal dogs were transduced with rAAV-*lacZ* serotypes 2 and 8 (Table 1). Prominent expression of β -gal was observed in the rAAV8-*lacZ*-injected muscles, whereas the rAAV2-*lacZ*-injected muscles showed minimal transgene expression (Figure 1). While β -gal expression in the rAAV8-injected muscle was correlated with the viral dose,

β -gal expression in the rAAV2-injected muscle was not augmented with viral dose escalation. However, rAAV8-*lacZ*-injected muscles, which showed extensive β -gal expression at 2 weeks, also exhibited reduced expression at 4 weeks after the injection, thereby suggesting that the transgene product had immunogenicity (Supplementary Figure S2).

To evaluate the difference in transduction efficiency between rAAV2 and rAAV8 at 2 weeks after the injection, relative quantifications of the vector genome and mRNA were performed. The result demonstrated higher transduction rates in the rAAV8-injected muscles as increasing amounts of the vector were administered (Figure 2a,b). The amount of protein expression was also well correlated with that of transgenic DNA (Figure 2c, Supplementary Table S1). Immunohistochemical analysis revealed that the rAAV2-injected muscles showed much more infiltration of CD4⁺ and CD8⁺ T lymphocytes in the endomysial space than the rAAV8-injected muscles did (Figure 3a). mRNA levels of TGF- β 1 and IL-6 (representative markers of inflammation) in the rAAV-injected muscles were standardized with the β -gal expression. rAAV2-injected muscles had higher TGF- β 1 and IL-6 expression than rAAV8-transduced muscles (Supplementary Figure S3). We also examined humoral immune responses against the rAAV particles in the sera of rAAV-injected dogs. The levels of serum IgG in reaction to rAAV2 or rAAV8 gradually increased with time in both serotypes (Figure 3b). These results suggest

that cellular and humoral immune responses are elicited in both rAAV2- and rAAV8-transduced muscles.

Bone marrow-derived DC reactions to rAAV2 and rAAV8

We next cultured bone marrow-derived DCs to investigate their response to rAAV injection in dogs. Flow cytometric analyses of these cells at 7 days of culture revealed marked expressions of CD11c and MHC class II molecules on the

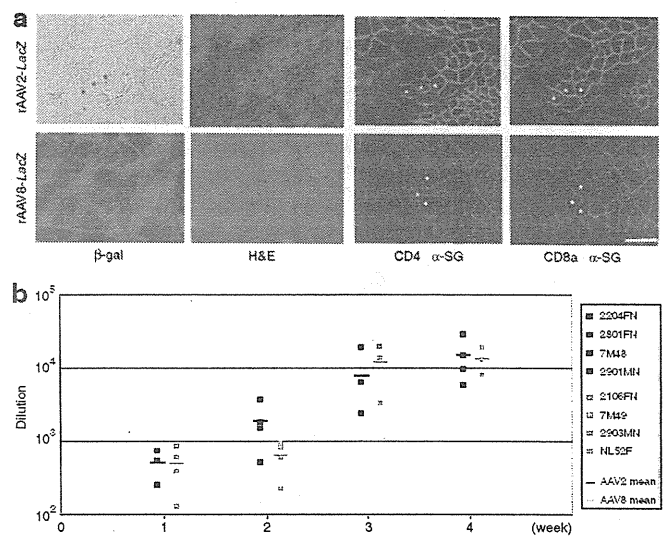

Figure 3 Immune response to rAAV. **(a)** Lymphocyte infiltration after rAAV transduction. Muscles were biopsied 2 weeks after rAAV2- or rAAV8-*lacZ* injection (2×10^{12} vg/muscle). Serial cross-sections were stained with β -gal and H&E, and were immunohistochemically stained with antibodies against canine CD4, CD8a (Alexa 568, red), and α -sarcoglycan (α -SG, Alexa 488, green). Upper: rAAV2-*lacZ*-injected TA muscle; lower: rAAV8-*lacZ*-injected TA muscle. Bar = 100 μ m. **(b)** Humoral immune responses to rAAV capsid in dogs. Serum was collected weekly from rAAV2- or rAAV8-*lacZ*-injected dogs and analyzed for the presence of IgG antibody against the rAAV2 or rAAV8 capsid. The data represent dilution rates with 50% reactivity of anti-rAAV2 (black boxes) and anti-rAAV8 (gray boxes) capsid antibodies. The mean reconstitution values are shown as straight lines. Each symbol represents an individual dog that was injected with rAAV at 2×10^{12} vg/muscle.

surface (Figure 4a,b). The DCs were cultured with the rAAV-*luciferase* of either serotype 2 or 8 for 48 hours to evaluate transduction efficiency, or cultured with rAAV-*lacZ* for 4 hours to investigate kinetic changes in mRNA. The luciferase assay showed that the transduction efficiency of rAAV2-*luciferase* in DCs was approximately two times that of rAAV8-*luciferase* (Figure 4c). mRNA levels of MyD88 and costimulating factors, such as CD80, CD86, and type I interferon (interferon- β , IFN- β) were elevated in both conditions (Figure 4d), suggesting that rAAV8 also induces a considerable degree of innate immune response in dog skeletal muscles. Although rAAV2-transduced DCs showed higher IFN- β expression than rAAV8-transduced DCs, the differences between the effects of rAAV2 and rAAV8 on the mRNA levels of MyD88, CD80, CD86, and IFN- β were not statistically significant.

Successful microdystrophin gene transfer with rAAV8 into dystrophic dogs

Dystrophin expression in normal skeletal muscle is localized on the sarcolemma, whereas it is totally absent in CXMD₁ dogs (Supplementary Figure S4a,b). Microdystrophin expression in the rAAV8-injected skeletal muscle of CXMD₁ dogs was maintained, even in the absence of any immunosuppressive therapy, for at least 4 weeks after the injection (Table 1). Previously, we had shown that microdystrophin expression of ca 20% was sufficient to achieve functional recovery in mdx mice⁶. However, the amount of the expression in intramuscularly injected muscles
