FIG. 3. FISH analyses of the patient. Arrow head indicates the deletion at 7q31.31.

[2010] characterized a de novo complex rearrangement of the long arm of chromosome 7 in a female patient with moderate mental retardation, anxiety disorder, and autistic features and suggested that disruption of the *C7orf58* gene contributed to the anxiety disorder, and autistic features of their patient. The *C7orf58* gene was also deleted in our patient. However, there have been no basic studies on the association of the *C7orf58* gene and brain function. Further studies are necessary on the role of the *C7orf58* gene.

Sadakata et al. [2007b] studied the behavior of *Cadps2−/−* mice. They showed impaired social interaction, hyperactivity, decreased exploratory behavior, and/or increased anxiety in a novel environment and deficits in intrinsic sleep–wake regulation and circadian rhythmicity. In addition, maternal neglect of newborns was a striking feature. They identified that *Cadps2−/−* mice show deficient release of NT-3 and BDNF. Cerebellar development was impaired in the mice. Sadakata et al. [2007a] found an aberrant alternatively spliced *CADPS2* mRNA that lacks exon 3 in some autistic patients. Exon 3 was shown to encode the dynactin 1-binding domain and affect axonal CADPS2 protein distribution. Exon 3-skipped CADPS2 protein possesses almost normal BDNF releasing activity but is not properly transported into the axons of neocortical or cerebellar neurons. However, Eran et al. [2009] observed no difference in prevalence of exon 3 skipping between ASDs and control samples. They concluded that exon 3 skipping represents a normal, minor isoform of CADPS2 in the cerebellum and is likely not a mechanism underlying autism susceptibility or pathogenesis. Our result may reinforce the evidence that *CADPS2* is associated with ASDs.

Cisternas et al. [2003] studied *CADPS2* gene mutations in 90 unrelated autistic individuals. However, they identified no disease-specific variants. Their results indicate that *CADPS2* mutations are not a major cause of ASDs. However, although small deletions of *CADPS2* as found in the present patient, might be rare, they support the idea that *CADPS2* abnormalities are associated with autism susceptibility.

Nikopoulos et al. [2010] reported two missense mutations in five of 11 FEVR families, indicating that mutations in *TSPAN12* are a relatively frequent cause of FEVR. Both residues are completely conserved throughout vertebrate evolution. These authors suggested that both haploinsufficiency and a dominant-negative effect of the mutant TSPAN12 on the wild-type protein should be considered as underlying disease mechanisms. Poulter et al. [2010] described mutations in the *TSPAN12* gene in FEVR patients and suggested that haploinsufficiency of *TSPAN12* causes FEVR because at least four of the seven mutations are predicted to lead to transcripts with premature-termination codons that are likely to be targeted by nonsense-mediated decay.

Recently, the Norrin/Frizzled4 signaling pathway that acts on the on the surface of developing endothelial cells and controls retinal vascular development is highlighted [Ye et al., 2010]. This pathway is composed of Norrin, its transmembrane receptor, Frizzled4, coreceptor, Lrp5, and an auxiliary membrane protein, Tspan12. The resulting signal controls a transcriptional program that regulates endothelial growth and maturation. PHPV and FEVR are associated with their pathogenesis. Our findings indicate that haploinsufficiency of *TSPAN12* is a plausible causative mechanism for PHPV. It will be interesting to study *TSPAN12* abnormalities in PHPV without *NDP* and *FZD4* mutations.

Singh et al. [2006] reported a voltage-gated potassium channel gene mutation in a temporal lobe epilepsy patient, namely a Kv4.2 truncation mutation lacking the last 44 amino acids in the carboxyl terminal. Kv4.2 channel is encoded by the *KCND2* gene. We suggest that the epileptic discharges on EEG reflect neuronal excitability caused by haploinsufficiency of *KCND2*.

Shen et al. [2010] suggested that using chromosomal microarray analysis to test for submicroscopic genomic deletions and duplications should be considered as part of the initial diagnostic evaluation of patients with ASDs. Miller et al. [2010] suggested that the use of chromosomal microarray is recommended as the first-tier cytogenetic diagnostic test for patients with unexplained developmental delay/intellectual disability, ASDs, or multiple congenital anomalies. In patients with ASDs and other anomalies, chromosomal microarray may be the useful method to clarify the underlying defect.

ACKNOWLEDGMENTS

We thank the patient's family for their cooperation. This study was supported by Health and Labour Research Grants from the Ministry of Health, Labour and Welfare of Japan.

Received 13 May 2011; Accepted 4 September 2011

We report on a patient with a submicroscopic deletion of 12q13 detected by array-CGH and confirmed by FISH. He was haploinsufficient for the *HOXC* gene cluster and some other neighboring genes. *HOX* genes have an important role in the initial formation of the body. The patient showed characteristic features including severe kyphoscoliosis, digital abnormalities, cardiac anomaly, expressive language, and global developmental delay. Radiologic features of the fingers had some similarities with those for multiple synostosis syndrome. No human genetic disorders due to *HOXC* abnormalities are yet known. We tentatively assume that his skeletal anomalies are associated with haploinsufficiency of the *HOXC* gene cluster. Further studies are necessary to determine the clinical importance of haploinsufficiency of the *HOXC* gene cluster.

Key words: *HOX*; *HOXC*; array-CGH; kyphoscoliosis; multiple synostosis syndrome

INTRODUCTION

HOX genes have an important role in the initial formation of the body plan by providing positional information along the anterior–posterior body and limb axis and are associated with neural tube closure. *HOX* A, B, C, and D make a cluster on chromosomes 7, 17, 12, and 2, respectively. Each cluster consists of 9–11 genes from 13 paralogous groups. The order of the *HOX* genes along the chromosome correlates with their expression along the anterior/posterior axis of the embryo.

Some of the *HOX* genes are associated with genetic syndromes. Akarsu et al. [1996] reported that a polyalanine tract expansion in *HOXD13* causes synpolydactyly (OMIM #186000). Mortlock and Innis [1997] found a nonsense mutation in *HOXA13* among patients with hand-foot-genital syndrome (OMIM #140000). Thompson and Nguyen [2000] reported that megakaryocytic thrombocytopenia and radio-ulnar synostosis (OMIM #605432) are associated with *HOXA11* mutations. Shrimpton et al. [2004] reported a *HOXD10* mutation in a family with isolated congenital vertical talus and Charcot-Marie-Tooth disease (OMIM #142984). Tischfield et al. [2005] identified homozygous truncating mutations in *HOXA1* in patients with horizontal gaze abnormalities, deafness, facial weakness, hypoventilation, vascular malformations of the internal carotid arteries and cardiac outflow tract, intellectual disability, and autism spectrum disorder. Two syndromes associated with homozygous mutations of *HOXA1* are known as the Bosley-Salih-Alorainy syndrome and the Athabascan brainstem dysgenesis syndrome (OMIM #601536) [Bosley et al., 2008]. Alasti et al. [2008] reported a mutation in *HOXA2* in autosomal-recessive microtia (OMIM #612290).

Spitz et al. [2002] reported a t(2;8)(q31;p21) balanced translocation with breakpoints near the human *HOXD* complex. The patient had mesomelic dysplasia of the upper limbs and vertebral defects. Dlugaszewska et al. [2006] reported three patients with limb abnormalities and breakpoints involving chromosome 2q31. None of the three 2q31 breakpoints, which all mapped close to the *HOXD*

cluster, disrupted any known genes. They suggested that the three rearrangements disturb normal *HOXD* gene regulation by position effects. Yue et al. [2007] reported a boy with severe intellectual disability, funnel chest, bell-shaped thorax, and hexadactyly of both feet. The patient had a balanced de novo t(12;17)(p13.3;q21.3) translocation. The breakpoint was near the *HOXB* cluster. They proposed that misregulation of a *HOXB* gene(s) by position effect is responsible for the patient's phenotype. Jun et al. [2011] reported a patient with the *HOXA* cluster deletion with manifestations similar to those observed in hand-foot-genital syndrome, which is caused by a haploinsufficiency of *HOXA13*.

We report on a patient with distinctive skeletal anomalies with a submicroscopic deletion of 12q13. He was haploinsufficient for the *HOXC* gene cluster. So far, no human genetic disorders due to *HOXC* abnormalities are reported. We discuss the clinical features in the patient and the haploinsufficiency of the *HOXC* genes.

CLINICAL REPORT

The 14-year-old male propositus was the first-born child of a 26-year-old mother and a 30-year-old father, both healthy and non-consanguineous. After an uncomplicated pregnancy, he was born at 39 weeks of gestation by induced delivery. His length was 53 cm (90th centile). His birth weight was 3,010 g, within normal limits (25th centile). After birth, cardiac murmur was noticed. Echocardiography revealed tetralogy of Fallot. Cardiac surgery was carried out successfully at 2 years of age. Surgery for bilateral inguinal hernia and strabismus was done at 3 years of age. His dentition was abnormal. Persistent teeth erupted before the loss of primary teeth. He showed hypodontia.

His development was delayed since early infancy. From the age of 6 months, he received physical training for delayed motor development. He was able to roll over at 10 months of age, and to sit alone at 3 years of age. He started to walk independently at 5 years of age and the spine deformity appeared. His global development quotient was 20 at 3 years of age. He attended special education in school. Gradually, he could understand simple words. His intellectual quotient remained around 30 and verbal production was almost absent. However, recently he could express simple sentences using key boards.

Physical examination identified dysmorphic features, including a long face, a broad nose, prominent ears, bilateral low-set ears, downslanting palpebral fissures and a high palate. Severe kyphosis and mild scoliosis were remarkable features. The radial heads were dislocated bilaterally. Camptodactyly of middle and ring fingers, inflexible distal interphalangeal joints of index fingers and adducted thumbs of both hands were noted (Fig. 1A). Hearing and visual acuity were normal. His weight was 29 kg (<3rd centile), and his length was 160 cm (<3rd centile). His head circumference was average for his age, 14 years.

Radiographic analysis revealed severe kyphosis and mild scoliosis in the thoracic spine (Fig. 2A,B). The upper thorax was mildly narrowed. The proximal interphalangeal joints of both the middle and ring fingers showed flexion contracture with para-articular swelling (Fig. 1B). The proximal interphalangeal joints of both index fingers were swollen as well. The metacarpophalangeal joint of the right index finger and proximal interphalangeal joint of the left little finger showed ulnar deviation. The metacarpals were mildly undertubulated. Radiologic features of the fingers were like those seen in multiple synostosis syndrome. However, no carpal or tarsal coalition was found.

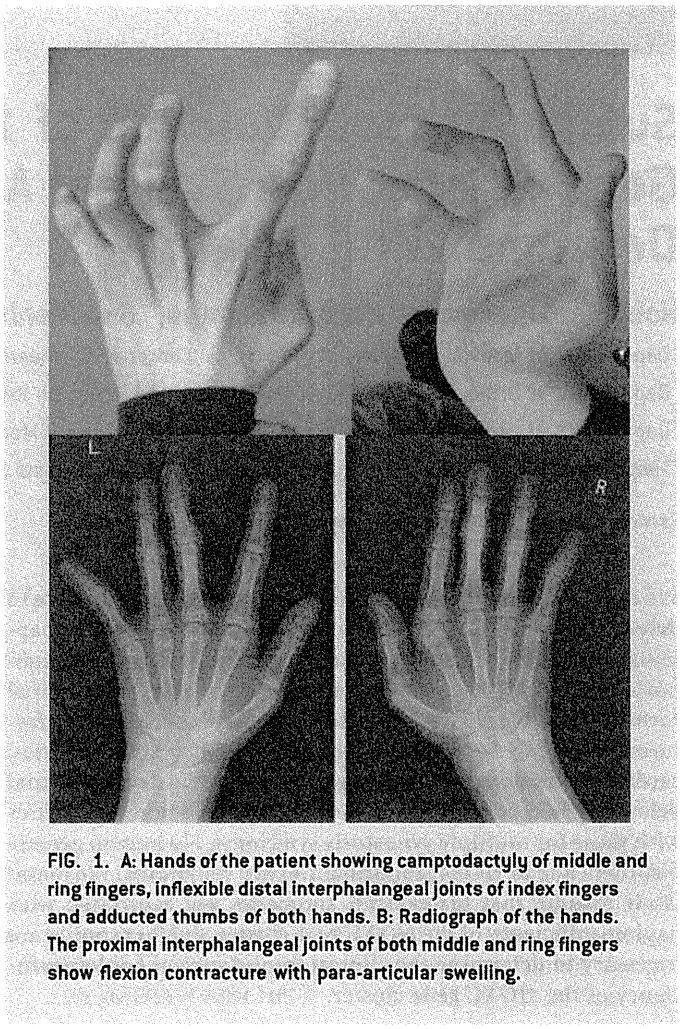

FIG. 1. A: Hands of the patient showing camptodactyly of middle and ring fingers, inflexible distal interphalangeal joints of index fingers and adducted thumbs of both hands. B: Radiograph of the hands. The proximal interphalangeal joints of both middle and ring fingers show flexion contracture with para-articular swelling.

Results of neuroradiological examinations including brain CT and MRI were normal. Routine laboratory tests were normal. His karyotype by G-banded analysis was 46,XY. Array-CGH analyses were performed to look for submicroscopic chromosomal aberrations.

MATERIALS AND METHODS

After obtaining informed consent and the permission of the institution's ethics committee, peripheral blood samples were drawn from the patient and his parents. Genomic DNA was extracted using the QIAquick DNA extraction kit (Qiagen, Valencia, CA).

Based on the hypothesis that the patient might have submicroscopic chromosomal aberrations, array-CGH analysis was performed using the Human Genome CGH Microarray 60K (Agilent Technologies, Santa Clara, CA) as described previously [Shimojima et al., 2009].

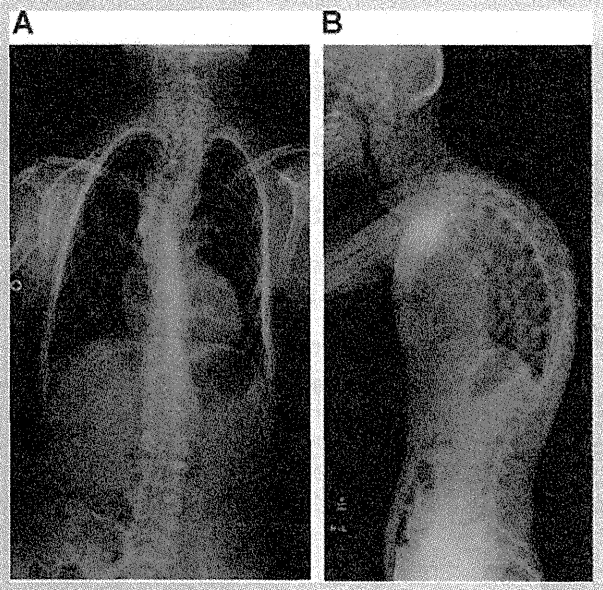

FIG. 2. Radiographs of the spine. A: Frontal view showing severe kyphosis and mild scoliosis in the thoracic spine. The upper thorax is mildly narrow. B: Lateral view.

Metaphase nuclei were prepared from peripheral blood lymphocytes by standard methods and used for FISH with human BAC clones selected from the UCSC genome browser (http://www.genome.ucsc.edu) as described elsewhere [Shimojima et al., 2009]. Physical positions refer to the March 2006 human reference sequence (NCBI Build 36.1).

RESULTS

By array-CGH analysis, loss of genomic copy numbers was identified in the region 12q13, which included the *HOXC* cluster (Fig. 3). The size of the deletion was 1.7 Mb. FISH analyses confirmed the deletion (see Supplementary Fig. A). FISH analyses of the parents found the deletion was de novo (data not shown). The karyotype of the patient was arr 12q13.1 (51,965,307-53,642,659)×1 dn.

DISCUSSION

A patient with distinctive skeletal anomalies had a submicroscopic deletion of 12q13 including *HOXC* gene cluster. His features included tetralogy of Fallot, abnormal dentition, and global developmental delay. This is the first report of *HOXC* gene cluster deletion. Human genetic disorders due to *HOXC* abnormalities are not known.

There have been multiple knock out studies on *Hoxc* genes. *Hoxc-4* is expressed in the most anterior regions of the CNS and prevertebral column. *Hoxc-4* mutant (−/−) mice showed a partial posterior homeotic transformation of the 7th cervical vertebra [Saegusa et al., 1996]. In addition, anterior transformations of the 3rd and 8th thoracic vertebrae, and an aperture or a fissure in the xiphoid process of the sternum were observed. No obvious defects were observed in the CNS. *Hoxc-4* (−/−) mice manifested vertebral defects that extended from the 2nd to 11th thoracic vertebra and died because of esophageal stenosis [Boulet and Capecchi, 1996].

Hoxc-8 is expressed in the limbs, backbone rudiments, and neural tube of mouse midgestation embryos, and in the cartilage and skeleton of newborns. Le Mouellic et al. [1992] generated *Hoxc-8* (−/−) mice. The mice were born alive, but most of them died within a few days. Anterior transformation in the several skeletal segments was characteristic. The 8th pair of ribs attached to the sternum and the 14th pair of ribs appeared on the 1st lumbar vertebra. During embryogenesis, *Hoxc-8* is highly expressed in motoneurons within spinal cord segments C7 to T1. These motoneurons innervate forelimb distal muscles that move the forepaw. *Hoxc-8*-deficient mice showed a congenital prehension deficiency of the forepaw due to abnormal innervation [Tiret et al., 1998].

Suemori et al. [1995] generated *Hoxc-9* mutant mice. Homozygous mice showed an anterior homeotic transformation from the 10th thoracic vertebra to the first lumbar vertebra. Bending and fusion of the ribs were observed. Eight or nine pairs of ribs were attached to the sternum. The sternum showed an abnormal pattern of ossification. Phenotypes of the mutant mice resembled those of the *Hoxc-8* mutant mice. Functional interaction between *Hoxc-8* and *Hoxc-9* during segmental determination was suspected.

Godwin and Capecchi [1998] reported *Hoxc-13* expression in the nails, tail, vibrissae, and filiform papillae of the tongue, and in hair follicles throughout the body. Mice homozygous for mutant alleles of *Hoxc-13* show brittle hair resulting in alopecia.

Suemori and Noguchi [2000] produced *Hox C* cluster null (−/−) mice. These mice die soon after birth with minor transformations. Perinatal death of the *HoxC* cluster (−/−) mutant mice is thought to be attributable to a neuromuscular defect in respiratory organs. Gross appearance of the skeleton and internal organs was almost normal. The mutant mouse showed subtle vertebral and rib anomalies. Malformations in the skeleton were even milder than those observed in some single gene mutant mice of *HoxC* genes. This means that at least some genes within a cluster interact with each other. The phenotype of *HoxC* cluster (+/−) mice, which have a similar genetic condition to our patient, was normal.

The phenotype of knockout mice does not always correspond to human disorders. Skeletal manifestations in our patient were not evident in his early childhood. Skeletal changes may progress during growth. Interestingly, translocation breakpoint near *HOXB* and *HOXD* with positional effect caused thoracic deformities and digital abnormalities [Spitz et al., 2002; Dlugaszewska et al., 2006; Yue et al., 2007]. We tentatively assume that skeletal anomalies in our patient are associated with haploinsufficiency of the *HOXC* gene cluster.

Radiologic features of the fingers had some similarities with those for multiple synostosis syndrome (OMIM #186500). Shi et al. [1999] found that Smad1 dislodges Hoxc-8 from its DNA-binding element and result in the induction of gene expression. Bone morphogenetic proteins (BMPs) induce osteoblast differentiation and bone formation. Smad1 mediates signaling initiated by BMPs and activates osteopontin and osteoprotegerin gene expression by dislodging Hoxc-8 from its DNA-binding sites [Liu et al., 2004].

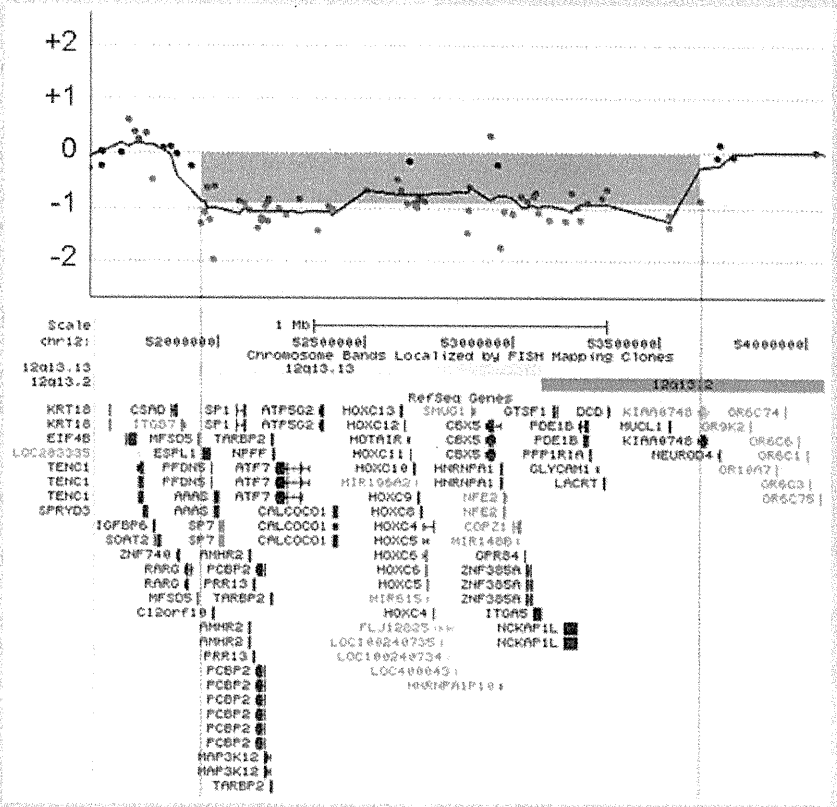

FIG. 3. Array-CGH revealed a loss of genomic copy numbers in the region 12q13, which included the *HOXC* cluster.

These findings indicate that *HOXC8* deficiency may induce osteogenesis by activating osteopontin and osteoprotegerin. The manifestations similar to the multiple synostosis syndrome, the flexion contracture and other digital abnormalities in our patient, may have some association with the *HOXC8* haploinsufficiency.

The multiple genes involved in the deletion may contribute to the manifestations. Our patient was haploinsuffient for *SP7/OSX*, *AAAS*, and *AMHRII*. Lapunzina et al. [2010] reported a homozygous single base pair deletion (c.1052delA) in *SP7/OSX* in an Egyptian child with recessive osteogenesis imperfecta (OMIM #613849). *SP7/OSX* plays a key role in human bone development. The triple-A syndrome (OMIM #231550) is caused by mutation in the gene-encoding aladin (*AAAS*; OMIM 605378). The anti-Müllerian hormone type II (AMHRII) receptor is the primary receptor for anti-Müllerian hormone (AMH), a protein responsible for the regression of the Müllerian duct in males. Mutations in the *AMHRII* gene lead to persistent Müllerian duct syndrome (OMIM #261550) in human males [Belville et al., 2009]. These syndromes are transmitted in autosomal recessive fashion and are not responsible for the manifestations in our patient. A haploinsufficiency of other genes may contribute to cardiac anomalies, dental anomalies, and intellectual disability with severe expressive language delay. Some of the deleted genes including *GPR84*, *PDE1B*, and *NPFF* are expressed in the nervous system. However, contribution of these genes to language development is unclear.

In conclusion, we report on a patient with distinctive skeletal anomalies and intellectual disability with a submicroscopic deletion of 12q13 including *HOXC* gene cluster. No human genetic disorders due to *HOXC* abnormalities are yet known. We posit that his kyphoscoliosis and digital abnormalities may be associated with haploinsufficiency of the *HOXC* gene cluster. Further studies of patients with similar conditions are necessary to determine the clinical significance of haploinsufficiency of the *HOXC* gene cluster.

ACKNOWLEDGMENTS

We thank for the family for their cooperation. This study was supported by the Health and Labour Research Grants in 2010 by Ministry of Health, Labour and Welfare in Japan.

Clinical application of array-based comparative genomic hybridization by two-stage screening for 536 patients with mental retardation and multiple congenital anomalies

Shin Hayashi[1,2], Issei Imoto[1,3], Yoshinori Aizu[4], Nobuhiko Okamoto[5], Seiji Mizuno[6], Kenji Kurosawa[7], Nana Okamoto[1,8], Shozo Honda[1], Satoshi Araki[9], Shuki Mizutani[9], Hironao Numabe[10], Shinji Saitoh[11], Tomoki Kosho[12], Yoshimitsu Fukushima[12], Hiroshi Mitsubuchi[13], Fumio Endo[13], Yasutsugu Chinen[14], Rika Kosaki[15], Torayuki Okuyama[15], Hirotaka Ohki[16], Hiroshi Yoshihashi[17], Masae Ono[18], Fumio Takada[19], Hiroaki Ono[20], Mariko Yagi[21], Hiroshi Matsumoto[22], Yoshio Makita[23], Akira Hata[24] and Johji Inazawa[1,25]

Recent advances in the analysis of patients with congenital abnormalities using array-based comparative genome hybridization (aCGH) have uncovered two types of genomic copy-number variants (CNVs); pathogenic CNVs (pCNVs) relevant to congenital disorders and benign CNVs observed also in healthy populations, complicating the screening of disease-associated alterations by aCGH. To apply the aCGH technique to the diagnosis as well as investigation of multiple congenital anomalies and mental retardation (MCA/MR), we constructed a consortium with 23 medical institutes and hospitals in Japan, and recruited 536 patients with clinically uncharacterized MCA/MR, whose karyotypes were normal according to conventional cytogenetics, for two-stage screening using two types of bacterial artificial chromosome-based microarray. The first screening using a targeted array detected pCNV in 54 of 536 cases (10.1%), whereas the second screening of the 349 cases negative in the first screening using a genome-wide high-density array at intervals of approximately 0.7 Mb detected pCNVs in 48 cases (13.8%), including pCNVs relevant to recently established microdeletion or microduplication syndromes, CNVs containing pathogenic genes and recurrent CNVs containing the same region among different patients. The results show the efficient application of aCGH in the clinical setting.

INTRODUCTION

Mental retardation (MR) or developmental delay is estimated to affect 2–3% of the population.[1] However, in a significant proportion of cases, the etiology remains uncertain. Hunter[2] reviewed 411 clinical cases of MR and reported that a specific genetic/syndrome diagnosis was carried out in 19.9% of them. Patients with MR often have congenital anomalies, and more than three minor anomalies can be useful in the diagnosis of syndromic MR.[2,3] Although chromosomal aberrations are well-known causes of MR, their frequency determined by conventional karyotyping has been reported to range from 7.9 to 36% in patients with MR.[4–8] Although the diagnostic yield depends on the population of each study or clinical conditions, such studies

suggest that at least three quarters of patients with MR are undiagnosed by clinical dysmorphic features and karyotyping.

In the past two decades, a number of rapidly developed cytogenetic and molecular approaches have been applied to the screening or diagnosis of various congenital disorders including MR, congenital anomalies, recurrent abortion and cancer pathogenesis. Among them, array-based comparative genome hybridization (aCGH) is used to detect copy-number changes rapidly in a genome-wide manner and with high resolution. The target and resolution of aCGH depend on the type and/or design of mounted probes, and many types of microarray have been used for the screening of patients with MR and other congenital disorders: bacterial artificial chromosome (BAC)-based arrays covering whole genomes,[9,10] BAC arrays covering chromosome X,[11,12] a BAC array covering all subtelomeric regions,[13] oligonucleotide arrays covering whole genomes,[14,15] an oligonucleotide array for clinical diagnosis[16] and a single nucleotide polymorphism array covering the whole genome.[17] Because genome-wide aCGH has led to an appreciation of widespread copy-number variants (CNVs) not only in affected patients but also in healthy populations,[18–20] clinical cytogenetists need to discriminate between CNVs likely to be pathogenic (pathogenic CNVs, pCNVs) and CNVs less likely to be relevant to a patient's clinical phenotypes (benign CNVs, bCNVs).[21] The detection of more CNVs along with higher-resolution microarrays needs more chances to assess detected CNVs, resulting in more confusion in a clinical setting.

We have applied aCGH to the diagnosis and investigation of patients with multiple congenital anomalies and MR (MCA/MR) of unknown etiology. We constructed a consortium with 23 medical institutes and hospitals in Japan, and recruited 536 clinically uncharacterized patients with a normal karyotype in conventional cytogenetic tests. Two-stage screening of copy-number changes was performed using two types of BAC-based microarray. The first screening was performed by a targeted array and the second screening was performed by an array covering the whole genome. In this study, we diagnosed well-known genomic disorders effectively in the first screening, assessed the pathogenicity of detected CNVs to investigate an etiology in the second screening and discussed the clinical significance of aCGH in the screening of congenital disorders.

MATERIALS AND METHODS

Subjects

We constructed a consortium of 23 medical institutes and hospitals in Japan, and recruited 536 Japanese patients with MCA/MR of unknown etiology from July 2005 to January 2010. All the patients were physically examined by an expert in medical genetics or a dysmorphologist. All showed a normal karyotype by conventional approximately 400–550 bands-level G-banding karyotyping. Genomic DNA and metaphase chromosomes were prepared from peripheral blood lymphocytes using standard methods. Genomic DNA from a lymphoblastoid cell line of one healthy man and one healthy woman were used as a normal control for male and female cases, respectively. All samples were obtained with prior written informed consent from the parents and approval by the local ethics committee and all the institutions involved in this project. For subjects in whom CNV was detected in the first or second screening, we tried to analyze their parents as many as possible using aCGH or fluorescence *in situ* hybridization (FISH).

Array-CGH analysis

Among our recently constructed in-house BAC-based arrays,[22] we used two arrays for this two-stage survey. In the first screening we applied a targeting array, 'MCG Genome Disorder Array' (GDA). Initially GDA version 2, which contains 550 BACs corresponding to subtelomeric regions of all chromosomes except 13p, 14p, 15p, 21p and 22p and causative regions of about 30 diseases already reported, was applied for 396 cases and then GDA version 3, which contains 660 BACs corresponding to those of GDA version 2 and pericentromeric regions of all chromosomes, was applied for 140 cases. This means that a CNV detected by GDA is certainly relevant to the patient's phenotypes. Subsequently in the second screening we applied 'MCG Whole Genome Array-4500' (WGA-4500) that covers all 24 human chromosomes with 4523 BACs at intervals of approximately 0.7 Mb to analyze subjects in whom no CNV was detected in the first screening. WGA-4500 contains no BACs spotted on GDA. If necessary, we also used 'MCG X-tiling array' (X-array) containing 1001 BAC/PACs throughout X chromosome other than pseudoautosomal regions.[12] The array-CGH analysis was performed as previously described.[12,23]

For several subjects we applied an oligonucleotide array (Agilent Human Genome CGH Microarray 244K; Agilent Technologies, Santa Clara, CA, USA) to confirm the boundaries of CNV identified by our in-house BAC arrays. DNA labeling, hybridization and washing of the array were performed according to the directions provided by the manufacturer. The hybridized arrays were scanned using an Agilent scanner (G2565BA), and the CGH Analytics program version 3.4.40 (Agilent Technologies) was used to analyze copy-number alterations after data extraction, filtering and normalization by Feature Extraction software (Agilent Technologies).

Fluorescence *in situ* hybridization

Fluorescence *in situ* hybridization was performed as described elsewhere[23] using BACs located around the region of interest as probes.

RESULTS

CNVs detected in the first screening

In the first screening, of 536 cases subjected to our GDA analysis, 54 (10.1%) were determined to have CNV (Figure 1; Tables 1 and 2).

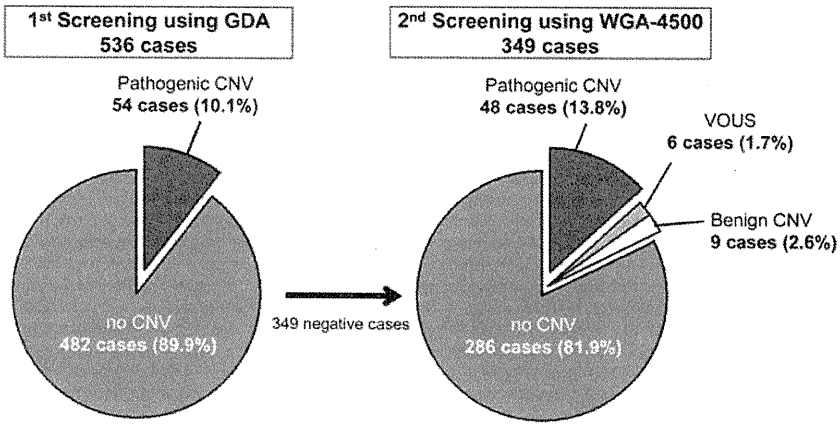

Figure 1 Percentages of each screening in the current study.

All the CNVs detected in the first screening were confirmed by FISH. Among the positive cases, in 24 cases one CNV was detected. All the CNVs corresponded to well-established syndromes or already described disorders (Table 1). In 16 cases two CNVs, one deletion and one duplication, were detected at two subtelomeric regions, indicating that one of parents might be a carrier with reciprocal translocation involved in corresponding subtelomeric regions, and at least either of the two CNVs corresponded to the disorders. We also performed parental analysis by FISH for three cases whose parental samples were available, and confirmed that in two cases the subtelomeric aberrations were inherited from paternal balanced translocation and in one case the subtelomeric aberrations were *de novo* (Table 1). In the other 14 cases, CNVs (25.9%) were detected in regions corresponding to known disorders (Table 2).

CNVs detected in the second screening and assessment of the CNVs

Cases were subject to the second screening in the order of subjects detected no CNV in the first screening, and until now we have analyzed 349 of 482 negative cases in the first screening. In advance, we excluded highly frequent CNVs observed in healthy individuals and/or in multiple patients showing disparate phenotypes from the present results based on an internal database, which contained all results of aCGH analysis we have performed using WGA-4500, or other available online databases; for example, Database of Genomic Variant (http://projects.tcag.ca/variation/). As a result, we detected 66 CNVs in 63 cases (Figure 1; Table 3). Among them, three patients (cases 36, 42 and 44) showed two CNVs. All the CNVs detected in the second screening were confirmed by other cytogenetic methods including FISH and/or X-array. For 60 cases, we performed FISH for confirmation and to determine the size of each CNV. For five cases, cases 13, 36, 48, 57 and 63, with CNVs on the X chromosome, we used the X-array instead of FISH. For cases 4, 6, 16–19 and 34, we also used Agilent Human Genome CGH Microarray 244K to determine the refined sizes of CNVs. The maximum and minimum sizes of each CNV determined by these analyses are described in Table 3.

Well-documented pCNVs emerged in the second screening

CNVs identified for recently established syndromes. We assessed the pathogenicity of the detected CNVs in several aspects (Figure 2).[21,37,38] First, in nine cases, we identified well-documented pCNVs, which are responsible for syndromes recently established. A heterozygous deletion at 1q41–q42.11 in case 2 was identical to patients in the first report of 1q41q42 microdeletion syndrome.[39] Likewise a CNV in case 3 was identical to chromosome 1q43–q44 deletion syndrome (OMIM: #612337),[40] a CNV in case 4 was identical to 2q23.1 microdeletion syndrome,[41] a CNV in case 5 was identical to 14q12 microdeletion syndrome[42] and a CNV in case 6 was identical to chromosome 15q26-qter deletion syndrome (Drayer's syndrome) (OMIM: #612626).[43] Cases 7, 8 and 9 involved CNVs of different sizes at 16p12.1-p11.2, the region responsible for 16p11.2-p12.2 microdeletion syndrome.[44,45] Although an interstitial deletion at 1p36.23-p36.22 observed in case 1 partially overlapped with a causative region of chromosome 1p36 deletion syndrome (OMIM: #607872), the region deleted was identical to a proximal interstitial 1p36 deletion that was recently reported.[46] Because patients with the proximal 1p36 deletion including case 1 demonstrated different clinical characteristics from cases of typical chromosome 1p36 deletion syndrome, in the near term their clinical features should be redefined as an independent syndrome.[46]

CNVs containing pathogenic gene(s). In four cases we identified pCNVs that contained a gene(s) probably responsible for phenotypes. In case 10, the CNV had a deletion harboring *GLI3* (OMIM: *165240) accounting for Greig cephalopolysyndactyly syndrome (GCS; OMIM: 175700).[47] Although phenotypes of the patient, for example, pre-axial polydactyly of the hands and feet, were consistent with GCS, his severe and atypical features of GCS, for example, MR or microcephaly, might be affected by other contiguous genes contained in the deletion.[48] Heterozygous deletions of *BMP4* (OMIM: *112262) in case 11 and *CASK* (OMIM: *300172) in case 13 have been reported previously.[49,50] In case 12, the CNV contained *YWHAE* (OMIM: *605066) whose haploinsufficiency would be involved in MR and mild CNS dysmorphology of the patient because a previous report demonstrated that haploinsufficiency of *ywhae* caused a defect of neuronal migration in mice[51] and a recent report also described a microdeletion of *YWHAE* in a patient with brain malformation.[52]

Recurrent CNVs in the same regions. We also considered recurrent CNVs in the same region as pathogenic; three pairs of patients had overlapping CNVs, which have never been reported previously. Case 16 had a 3.3-Mb heterozygous deletion at 10q24.31–q25.1 and case 17 had a 2.0-Mb deletion at 10q24.32–q25.1. The clinical and genetic information will be reported elsewhere. Likewise, cases 14 and 15 also had an overlapping CNV at 6q12–q14.1 and 6q14.1, and cases 18 and 19 had an overlapping CNV at 10p12.1–p11.23. Hereafter, more additional cases with the recurrent CNV would assist in defining new syndromes.

CNVs reported as pathogenic in previous studies. Five cases were applicable to these criteria. A deletion at 3p21.2 in case 20 overlapped with that in one case recently reported.[53] The following four cases had CNVs reported as pathogenic in recent studies: a CNV at 7p22.1 in case 21 overlapped with that of patient 6545 in a study by Friedman *et al.*,[14] a CNV at 14q11.2 in case 22 overlapped with those of patients 8326 and 5566 in Friedman *et al.*,[14] a CNV at 17q24.1–q24.2 in case 23 overlapped with that in patient 99 in Buysse *et al.*[54] and a CNV at 19p13.2 in case 24 overlapped with case P11 in Fan *et al.*[55]

Large or gene-rich CNVs, or CNVs containing morbid OMIM genes. In cases inapplicable to the above criteria, we assessed CNVs

Table 3 Sixty-three cases with CNV in the 2nd screening

Abbreviations: aRS, atypical Rett syndrome; B, benign; CNV, copy-number variant; *dn*: *de novo* CNV observed in neither of the parents; ELBW, extremely low birth weight; FISH, fluorescence *in situ* hybridization; GS, Gillespie syndrome; *mat*: CNV identified also in mother; P, pathogenic; *pat*: CNV identified also in father; RTS, Rubinstein–Taybi syndrome; SMS, Smith–Magenis syndrome; VOUS, variant of uncertain clinical significance; ZLS, Zimmermann–Laband syndrome.
[a]The sizes were estimated by WGA-4500, X-array, FISH or Agilent Human Genome CGH microarray 244K.
[b]The notation systems is based on ISCN2005.[36]
[c]The number of protein-coding genes contained in the respective CNVs.
[d]The result of CNV assessment.

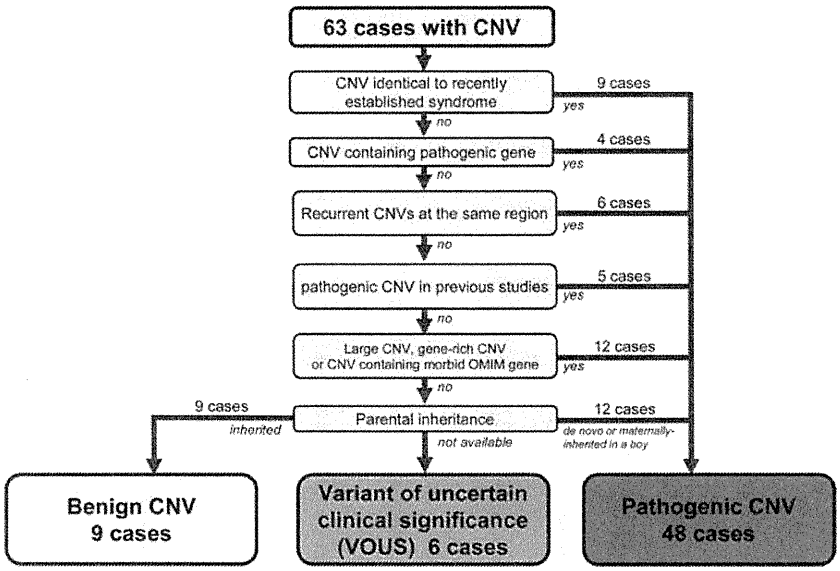

Figure 2 A flowchart of the assessment of CNVs detected in the second screening.

from several aspects. A CNV that contains abundant genes or is large (>3 Mb) has a high possibility to be pathogenic.[21] The CNVs in cases 25–30 probably correspond to such CNVs. Also, we judged a CNV containing a morbid OMIM gene as pathogenic:[21] *TBR1* (OMIM: *604616) in case 31,[56] *SUMF1* (OMIM: *607939) in case 32,[57,58] *SEMA3A* (OMIM: *603961) in case 33,[59] *EML1* (OMIM: *602033) and/or *YY1* (OMIM: *600013) in case 34,[60,61] *A2BP1* (OMIM: *605104) in case 35[62] and *IL1RAPL1* (OMIM: *300206) in case 36.[63] Several previous reports suggest that these genes are likely to be pathogenic, although at present no evidence of a direct association between these genes and phenotypes exists.

CNVs de novo or X maternally inherited. Among the remaining 27 cases, 12 cases had CNVs considered pathogenic as their CNVs were *de novo* (cases 37–47) or inherited del(X)(p11.3) from the mother (case 48). In the second screening we performed FISH for 36 CNVs of the 34 cases whose parental samples were available to confirm that 24 cases had *de novo* CNVs, which were probably pathogenic. A CNV in case 48, a boy with a nullizygous deletion at Xp11.3 inherited from his mother, was also probably relevant to his phenotype (Tables 3 and 4). Meanwhile, although case 57 was a boy with a deletion at Xp11.23 inherited from his mother, he was clinically diagnosed with Gillespie syndrome (OMIM: #206700) that was reported to show an autosomal dominant or recessive pattern,[64] thus we judged that the deletion was not relevant to his phenotype. As a result, cases 49–57 had only CNVs inherited from one of their parents which are likely to be unrelated to the phenotypes; that is, bCNV (Table 4).

As a result, we estimated that 48 cases among 349 analyzed (13.8%) had pCNV(s) in the second screening (Table 3; Figure 2). The CNVs of the remaining six cases, cases 58–63, were not associated with previously reported pathogenicity and their inheritance could not be evaluated, thus we estimated they were variants of uncertain clinical significance (VOUS).[38]

DISCUSSION

Because aCGH is a high-throughput technique to detect CNVs rapidly and comprehensively, this technique has been commonly used for analyses of patients with MCA and/or MR.[38,65–68] However, recent studies of human genomic variation have uncovered surprising properties of CNV, which covers 3.5–12% of the human genome even in healthy populations.[18–20,69] Thus analyses of patients with uncertain clinical phenotypes need to assess whether the CNV is pathogenic or unrelated to phenotypes.[21] However, such an assessment may diminish the rapidness or convenience of aCGH.

In this study, we evaluated whether our in-house GDA can work well as a diagnostic tool to detect CNVs responsible for well-established syndromes or those involved in subtelomeric aberrations in a clinical setting, and then explored candidate pCNVs in cases without any CNV in the first GDA screening. We recruited 536 cases that had been undiagnosed clinically and studied them in a two-stage screening using aCGH. In the first screening we detected CNVs in 54 cases (10.1%). Among them, 40 cases had CNV(s) at subtelomeric region(s) corresponding to the well-established syndromes or the already described disorders and the other 14 cases had CNVs in the regions corresponding to known disorders. Thus about three quarters of cases had genomic aberrations involved in subtelomeric regions. All the subtelomeric deletions and a part of the subtelomeric duplications corresponded to the disorders, indicating that especially subtelomeric deletions had more clinical significance compared to subtelomeric duplications, although the duplication might result in milder phenotypes and/or function as a modifier of phenotypes.[70] Moreover, parental analysis in three cases with two subtelomeric aberrations revealed that two of them were derived from the parental balanced translocations, indicating that such subtelomeric aberrations were potentially recurrent and parental analyses were worth performing. Recently several similar studies analyzed patients with MCA/MR or developmental delay using a targeted array for subtelomeric regions and/or known genomic disorders and detected clinically relevant CNVs in 4.4–17.1% of the patients.[28,65,70,71] Our detection rate in the first screening was equivalent to these reports. Although such detection rates depend on the type of microarray, patient selection criteria and/or number of subjects, these results suggest that at least 10% of cases with undiagnosed MCA/MR and a normal karyotype would be detectable by targeted array.

Abbreviations: B, benign; CNV, copy-number variant; F, female; M, male; MCA/MR, multiple congenital anomalies and mental retardation; P, pathogenic.
[a]Two CNVs were detected in case 42.
[b]Two CNVs were detected in case 44.
[c]Nullizygous deletion inherited from his mother probably affected the phenotype.

Another interesting observation in the first screening was that subtelomeric rearrangements frequently occurred even in patients with MCA/MR of uncertain whose karyotype had been diagnosed as normal. This result may be consistent with a property of subtelomeric regions whose rearrangements can be missed in conventional karyotyping,[72] and in fact other techniques involving subtelomeric FISH or MLPA also identified subtelomeric abnormalities in a number of patients with MCA and/or MR in previous reports.[70,73,74] Our result may support the availability of prompt screening of subtelomeric regions for cases with uncertain congenital disorders.

In the second screening we applied WGA-4500 to 349 cases to detect 66 candidate pCNVs in 63 cases (18.1%), and subsequently assessed the pathogenicity of these CNVs. The pCNVs included nine CNVs overlapping identical regions of recently recognized syndromes (cases 1–9; deletion at 1p36.23–p36.22, 1q41–q42.11, 1q43–q44, 2q23.1, 14q12, 15q26-qter and 16p11.2–p12.2, respectively), four CNVs containing disease-associated genes (cases 10–13; *GLI3*, *BMP4*, *YWHAE* and *CASK*, respectively), three pairs of CNVs of recurrent deletions (cases 14, 15: at 6q12–q14.1 and 6q14.1; case 16, 17: at 10p12.1–p11.23 and case 18, 19: at 10q24.31–q25.1 and 10q24.32–q25.1), five CNVs identical to pCNVs in previous studies (cases 20–24), six large and/or gene-rich CNVs (cases 25–30) and six CNVs containing a morbid OMIM gene (cases 31–36). For the remaining cases, we estimated the pathogenicity of the CNVs from a parental analysis (Table 4). We judged the 11 *de novo* CNVs (cases 37–47) and 1 CNV on chromosome Xp11.3 inherited from

the mother (case 48) as probably pathogenic. And nine inherited CNVs (cases 49–57) were probably benign. The clinical significance of CNVs in the other six cases, cases 58–63, remains uncertain (VOUS). As a result we estimated CNVs as pathogenic in 48 cases among 349 cases (13.8%) analyzed in the second screening. None of the pCNVs corresponded to loci of well-established syndromes. This may suggest that our two-stage screening achieved a good balance between rapid screening of known syndromes and investigation of CNV of uncertain pathogenicity.

Table 5 Summary of parental analyses

		Average size (bp)		*The average number of protein-coding genes*
		Min.	*Max.*	
Pathogenic CNVs[a]				
del	23	3 309 267	4 597 689	43
dup	2	1 190 098	1 587 722	61
Total	25	3 139 733	4 356 892	44
Benign CNVs[b]				
del	3	538 481	1 030 504	10
dup	8	334 432	1 740 327	3
Total	11	390 082	1 546 739	5

Abbreviation: CNV, copy-number variant.
[a]Twenty-four *de novo* CNVs and case 48.
[b]Eleven inherited CNVs other than case 48.

Among the cases with parental analyses, the 25 pCNVs had larger sizes and contained more protein-coding genes (average size, 3.1 Mb at minimum to 4.4 Mb at maximum; average number of genes, 44) as compared with the 11 inherited bCNVs that were probably unrelated to phenotypes (average size, 0.39 Mb at minimum to 1.5 Mb at maximum; average number of genes, 5) (Table 5). Although all of the 25 pCNVs except 2 were deletions, about three quarters (8 of 11 cases) of the inherited bCNVs were duplications (Table 5). These findings are consistent with previously reported features of pCNVs and bCNVs.[21,38]

We also compared our current study with recent aCGH studies meeting the following conditions: (1) a microarray targeted to whole genome was applied; (2) patients with MCA and/or MR of uncertain etiology, normal karyotype and the criteria for patients selection were clearly described; (3) pathogenicity of identified CNVs were assessed. On the basis of the above criteria, among studies reported in the past 5 years, we summarized 13 studies (Table 6).[10,14,15,17,54,55,75–81] Diagnostic yield of pCNVs in each study was 6.3–16.4%, and our current diagnostic yield of the second screening was 13.8%. Though cases with subtelomeric aberration detected in the first screening had been excluded, our diagnostic yield was comparable to those of the reported studies. It is not so important to make a simple comparison between diagnostic yields in different studies as they would depend on the conditions of each study, for example, sample size or array resolution,[38,82] however it seems interesting that the higher resolution of a microarray does not ensure an increase in the rate of detection of pCNVs. One recent study showed data that may explain the discrepancy between the resolution of microarray and diagnostic yield.[54,83] The authors analyzed 1001 patients with MCA and/or MR using one

Abbreviations: BAC, bacterial artificial chromosome; CNV, copy-number variant; DD, developmental delay; MCA, multiple congenital anomalies; MR, mental retardation; SNP, single nucleotide polymorphism.
[a]The number of clones or name of array is described.
[b]Each distribution referred to each article (*) or manual of each manufacturer (**).
[c]All cases were analyzed by both a targeted array and a genome-wide array.
[d]In five cases, CNVs were also identified by a targeted array.
[e]Ten cases with an abnormal karyotype were excluded.
[f]Only cases studied with an array throughout the genome are described. Ninety-eight cases were also analyzed by a targeted array.
[g]Seventeen cases with an abnormal karyotype were excluded.
