ALK-positive cases. This finding is consistent with that of a previous report in which rhabdomyosarcoma cell lines were found not to harbor DNA copy number gain at the 2p23 locus, where the *ALK* gene is located.[39] Similarly, *ALK* was not found to be a differentially amplified gene when genomic imbalances were compared between primary rhabdomyosarcoma tissues and normal muscle.[39]

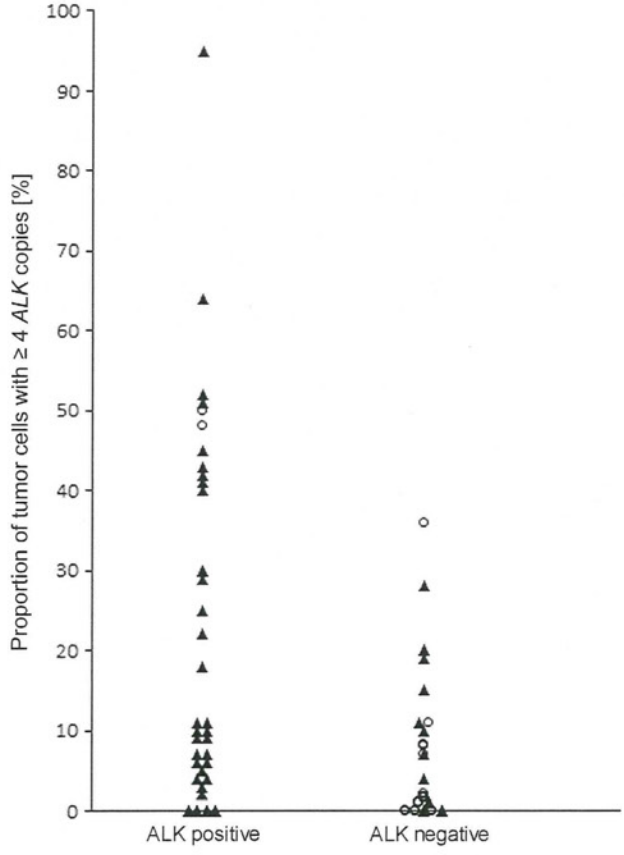

Figure 6 The percentage of tumor cells that harbored ≥4 copies of *ALK* gene determined by FISH in 37 ALK-positive and 23 ALK-negative rhabdomyosarcomas. ▲ indicates the alveolar subtype, and ○ indicates non-alveolar subtypes. ALK-positive tumors carried a significantly greater percentage of cells with ≥4 copies of the *ALK* gene than ALK-negative tumors did ($P=0.013$).

Our finding of a low incidence of increased *ALK* copy number in rhabdomyosarcoma was in contrast with the results of a recent large study by van Gaal *et al*[23] In their study, the absolute *ALK* copy number increased (>4 copies in >10% of cells) in 88% of alveolar rhabdomyosarcomas and 52% of embryonal tumors, and a selective *ALK* gain (average *ALK/LAF*>1.5) was seen in 45% of alveolar tumors and 61% of embryonal cases. The reason for this incongruence is unclear. Even when FISH interpretation criteria similar to theirs were applied, the *ALK* gain/amplification was uncommon in our cohort: tumors with >4 *ALK* copies in >10% of cells were observed in 23% of the alveolar tumors and 23% of the non-alveolar subtypes, and an average *ALK/CEN2p* of >1.5 was seen in 4% of the alveolar tumors and 15% of the non-alveolar cases. Other investigators also reported *ALK* gene gain/amplification in rhabdomyosarcoma (Table 4), but the number of cases studied was small, and the quantitative definition of gain/amplification was not provided.[19,20,22] Notably, these prior studies either did not use a reference probe[19,22] or separately examined the *ALK* gene and a reference gene,[20,23] whereas we simultaneously evaluated the *ALK* and reference genes using a dual-color approach that enabled precise determination of gene copy number at the cellular level.

ALK gene rearrangement and somatic mutation do not seem to have a major role in rhabdomyosarcoma. *ALK* rearrangement was not identified in any of the cases examined in this study, a finding similar to that of other studies.[20,22,23] Interestingly, one

Cessna *et al*[19] also separately evaluated p80 antibody, the results of which are not summarized here.

study[19] found *ALK* rearrangement in three of six rhabdomyosarcomas tested. We identified an *ALK* missense mutation (c.3830G>A, p.I1277T) in one embryonal rhabdomyosarcoma. However, this tumor was not immunopositive for ALK, indicating that the mutation may not be an activating one. This mutation was different from that (c.3673G>A, p.D1225N) reported previously in an embryonal rhabdomyosarcoma.[23] The same study[23] also identified frame-shift deletions in two alveolar and five embryonal rhabdomyosarcomas by cDNA sequencing, which probably represented alternative mRNA splicing;[23] we did not find any deletions in the genomic DNA.

The positive ALK immunoreactivity in a subset of rhabdomyosarcomas, some of which are associated with an *ALK* gene copy number increase, may suggest the potential clinical benefit of ALK inhibition. However, whether ALK expression without gene rearrangement has oncologic relevance remains controversial. Thus far, ALK-targeted therapy has been shown to be clinically effective only in *ALK*-rearranged tumors. Some researchers[40] argued that ALK expression in rhabdomyosarcoma may simply be physiological rather than oncogenic, by showing that the ALK-expressing Rh30 cell line lacked ALK autophosphorylation. In contrast, others[41–43] suggested that in neuroblastomas, ALK protein expression itself exerts oncogenic activity irrespective of genomic status and that it is a potential target of kinase inhibitors. Future clinical studies should investigate whether ALK inhibitors are beneficial for treating ALK-immunopositive tumors without gene rearrangement.

In summary, we clarified the subtype-specific incidence of ALK immunoreactivity in rhabdomyosarcomas and showed the association between ALK expression and several clinicopathologic/molecular parameters. This comprehensive analysis will serve as a basis for future investigations that aim to determine the indication, or lack thereof, of ALK-targeted therapy for patients with rhabdomyosarcoma.

Abstract
Purpose The prognosis of adult rhabdomyosarcoma (RMS) has been considered dismal. The question is raised that vincristine, *d*-actinomycin, and cyclophosphamide (VAC) chemotherapy may not be administered as per schedule for adult RMS; consequently, low dose intensity (DI) leads to poor prognosis. Herein, we examined whether the administration of VAC chemotherapy for adults and children with RMS is feasible with regard to the DIs of VAC.
Methods Chart review was retrospectively performed for all identified patients. The percentage of relative DI (RDI) was calculated according to the Children's Oncology Group D9803 protocol. Further, we examined the RDI in the first 6 cycles of VAC (induction phase) and the DI after the first 6 cycles of VAC (maintenance phase).
Results We identified a total of 27 adults and 18 children with RMS, respectively. The mean RDIs of vincristine in total phase were significantly lower in adults than that in children ($P = 0.04$). In induction phase, the mean RDIs of vincristine and cyclophosphamide were similar for both groups; however, they were dropped significantly in adults during maintenance phase ($P < 0.05$). Mean RDIs of vincristine in elderly patients tended to become low. Low RDI was mainly attributable to hematologic toxicity, infection, and peripheral neuropathy. The prognosis of low versus high RDI was similar.
Conclusions The RDIs of vincristine and cyclophosphamide in the maintenance phase were significantly lower than that in children. VAC chemotherapy for adults was not feasible; these patients require a different regimen.

RMS	Rhabdomyosarcoma
VAC	Vincristine, *d*-actinomycin, and cyclophosphamide
DI	Dose intensity
RDI	Relative dose intensity
IRS	The International Rhabdomyosarcoma Study
PFS	Progression-free survival
OS	Overall survival
PCP	Pneumocystis jirovecci pneumonia

Introduction

Recent advances in the treatment for rhabdomyosarcoma have contributed to improve survival from 55 to 73 % [1–3]. Vincristine and *d*-actinomycin with or without cyclophosphamide (VAC) regimens for rhabdomyosarcoma are considered standard options according to the previous randomized trials [4–8]. However, these trials

mainly focused on children or adolescents; therefore, the data of precious adult rhabdomyosarcoma patients were limited.

Sultan et al. [9] reported the prognosis of pediatric and adult rhabdomyosarcoma, and the data suggested that 5-year survival rate was significantly poor in adult rhabdomyosarcoma with 27 % compared to that of pediatrics with 61 %. Other facilities also reported small series of similar results [10–14]. Accordingly, the prognosis of adult rhabdomyosarcoma remained poor; however, the treatment strategy references along with childhood rhabdomyosarcoma.

There is no evidence available to uncover the reason for poor prognosis of adult rhabdomyosarcoma. The VAC chemotherapy was developed mainly for targeting pediatrics; therefore, adverse event may differ when we applied the regimen to adults. Accordingly, the VAC regimens may not be administered per schedule, which leads to poor prognosis due to low dose intensity. To our knowledge, there are no reports on dose intensity of VAC regimens in relation to prognosis. We launched this study to seek optimal treatment for adult rhabdomyosarcoma by comparing dose intensity to childhood or adolescent rhabdomyosarcoma.

Methods

Patients

All the patients included in this analysis meet the following criteria: histologically diagnosed with rhabdomyosarcoma, treated at the National Cancer Center Hospital in Tokyo between 1991 and 2010, and received VAC chemotherapy 6 cycles or over as a first-line treatment. The chart review was performed for all identified patients to obtain the following information: age, sex, primary tumor site, histopathology, tumor size, stage, group defined by the International Rhabdomyosarcoma Study (IRS) postsurgical grouping system [4], chemotherapy regimen, chemotherapy administration schedule, adverse event, date of radiotherapy, date of surgery, date of progression, and date of last follow-up.

Treatment

The details of VAC chemotherapy are shown as follows. VAC consisted of vincristine at a dose of 1.5 mg/m^2 (up to 2 mg/body), given intravenously on day 1, 8, 15, cyclophosphamide at a dose of 2.2 g/m^2, given intravenously on day 1, and *d*-actinomycin at a dose of 1.5 mg/m^2 (up to 2.5 mg/body), given intravenously on day 1. The treatment course was repeated every 3 weeks according to Children's Oncology Group Study D9803 [8]. *D*-actinomycin on day 1 and vincristine on day 8 and day 15 were omitted when radiotherapy was applicable.

Dose intensity calculation and definitions of terms

Dose intensity of vincristine and cyclophosphamide was calculated according to the following formula: Dose intensity (vincristine) = Total dose of vincristine (mg/m^2)/[(last date of injection − first date of injection) + 7]/7; Dose intensity (cyclophosphamide) = Total dose of cyclophosphamide (mg/m^2)/[(last date of injection − first date of injection) + 21]/7, respectively. The percentage of relative dose intensity (RDI) was calculated according to the Children's Oncology Group D9803 protocol [8]. We examined the RDI in induction phase and maintenance phase. Induction phase was defined as the first six cycles of VAC, and maintenance phase was defined as the latter cycles after induction phase. We defined cut-off points of RDI of vincristine and cyclophosphamide at 80 % and dichotomized into lower RDI (RDI $<$ 80 %) and higher RDI (RDI $\geq$ 80 %).

We defined adult as the patients aged greater than or equal to 21 years, and we used the term 'children' for the others. We attempted to retrospectively define the stage of disease according to the IRS staging system, which separates patients by site of the primary tumor, tumor size, and the presence or absence of tumor-involved regional lymph nodes and of distant metastases. Adverse events were retrospectively ranked by the National Cancer Institute Common Toxicity Criteria version 3.0. As a definition of febrile neutropenia, we used the guidelines established by the Infectious Disease Society of America [15]. Treatment delay was defined as more than a week of delay to start new cycle of VAC regimen.

Statistics

We used Student's *t* test to detect the difference of mean RDI. Progression-free survival (PFS) was defined as the time between the date of initial chemotherapy until the date of the recognition of local recurrence or distant metastases. Death was treated as an event, and the absence of disease progression was treated as a censored observation on the last day of follow-up. Overall survival (OS) was defined as the time from the date of initial chemotherapy until the date of death. Patients who were lost to follow up were treated as a censored observation on the last day of follow-up. We used the Kaplan–Meier method to draw survival curve, and significance was detected by the log-rank test. All statistical analyses were performed using SPSS ver. 19.0 (IBM Co. Inc, Okinawa, Japan).

Results

Patient characteristics

We identified 59 patients who received VAC regimen and of 45 patients met the eligibility criteria in the study period. Fourteen patients were excluded from this analysis by the following reasons: less than 6 cycles of VAC regimen in 12 patients, VAC chemotherapy of IRS II protocol in one, and clinical data unavailable in one. There were 27 adult patients and 18 were children.

The distribution of clinical and pathologic characteristics of these patients is listed in Table 1. The median age of adult was 28 years (range, 22–72) and that of children was 16 years (range, 2–19). Primary disease site, histopathology, and primary tumor size were similar among adult and children. Fourteen adults and 8 children had parameningeal primary site. Metastatic disease was somewhat high in adult.

Overall median follow-up period was 26 months (range, 6–114 months): 26 months in adults (range, 6–113 months) and 36 months in children (range, 6–114 months). We identified a total of 316 cycles of VAC chemotherapy in adults and a total of 209 cycles in children. The median number of chemotherapy cycles was 13 (range, 6–14) for adults and 12.5 (range, 6–14) for children.

Relative dose intensity of VAC chemotherapy

The mean RDIs of vincristine and cyclophosphamide in total phase for adults were 76.8 and 80.8 %, respectively, and those for children were 90.2 and 86.9 %, respectively. The mean RDI of vincristine in total phase was significantly lower in adults than that in children ($P < 0.05$) (Table 2).

In induction phase, the mean RDIs of vincristine and cyclophosphamide were similar for both groups; however, they were dropped significantly in adults during maintenance phase ($P < 0.05$) (Table 2). We examined the RDIs of vincristine and cyclophosphamide in relation to age. Mean RDIs of vincristine in elderly patients tended to become low (Fig. 1).

Chemotherapy efficacy by RDI

We analyzed the efficacy of RDI on PFS and OS. The PFS and OS were not statistically different in patients with high RDI and low RDI of vincristine and cyclophosphamide in total phase. For total phase of RDI for vincristine, median PFS was 28 months in patients with high RDI ($n = 15$) and 24 months in patients with low RDI ($n = 30$) ($P = 0.43$), and median OS was 60 months in patients with high RDI ($n = 15$) and 42 months in patients with low RDI ($n = 30$) ($P = 0.78$) (Fig. 2a). For total phase of RDI for cyclophosphamide, median PFS was 28 months in patients with high RDI ($n = 17$) and 24 months in patients with low RDI ($n = 28$) ($P = 0.78$), and median OS was 114 months in patients with high RDI ($n = 17$) and 60 months in patients with low RDI ($n = 28$) ($P = 0.67$) (Fig. 2b). We further analyzed induction phase and maintenance phase of RDIs for vincristine and cyclophosphamide or stratified them by adults and children on PFS and OS. None of the difference regarding RDI of both agents on PFS and OS was detected (Fig. 3).

Toxicity of VAC chemotherapy

Table 3 lists the worst degree of toxicity of VAC chemotherapy. Majority of patients experienced grade 3/4 neutropenia and anemia in both induction phase and maintenance phase. Grade 2–4 peripheral neuropathy was observed in 55.6 % of adult patients, while it was 33.3 % in children ($P = 0.37$). Approximately 80 % of patients needed granulocyte colony-stimulating factor, and 73.3 % of patients received trimethoprim-sulfamethoxazole for prevention of pneumocystis jirovecci pneumonia (PCP). Two patients who did not receive trimethoprim-sulfamethoxazole developed PCP; one experienced PCP in 4th cycle of VAC, and the other did in 14 the cycle of VAC.

Cause of dose reduction, skip, and delayed cycles

In induction phase, three of adults (11.1 %) and one of children (5.6 %) required dose reduction of vincristine due to peripheral neuropathy and myelosuppression. Eight of the patients (29.6 %) in adults and 4 of the patients (22.2 %) in children required dose reduction of cyclophosphamide, due to myelosuppression, febrile neutropenia, and liver dysfunction. In maintenance phase, four adults (16.0 %) and 2 children (11.8 %) required dose reduction of vincristine, due to peripheral neurotoxicity and myelosuppression. Nine adults (36.0 %) and 5 children (18.5 %) required dose reduction of cyclophosphamide, due to myelosuppression and febrile neutropenia.

Adult patients needed discontinuance of vincristine in total of 126 times out of 713 times (17.7 %) due to the following reasons: peripheral neurotoxicity in 75 times, myelosuppression in 35 times, and febrile neutropenia in 14 times. For these child patients, it was 55 times out of 483 times of vincristine administration (11.4 %) due to peripheral neurotoxicity in 16 times, myelosuppression in 16 times, and febrile neutropenia in 9 times.

In induction phase, 14 adult patients (51.9 %) and 9 child patients (50.0 %) experienced cycle delay. In maintenance phase, 17 adult patients (68.0 %) and 9 child patients (52.9 %) required cycle delay. The major causes of

cycle delay were myelosuppression, febrile neutropenia, and patient preferences.

Discussion

In our analyses, 27 adults and 18 children of rhabdomyosarcoma who received VAC chemotherapy at a single institution were evaluated for RDIs of VAC chemotherapy. Adult patients had significantly lower RDIs of vincristine and cyclophosphamide in the maintenance phase compared

to those of children. Further, the mean RDIs of vincristine tended to become low depending on patients' ages. The reasons for dose reduction, discontinuance, and treatment delay of vincristine and cyclophosphamide were generally due to myelosuppression, infection, and peripheral neurotoxicity. We revealed that the adult rhabdomyosarcoma patients significantly received lower RDIs of vincristine and cyclophosphamide than those of children; however, the PFS and the OS were not statistically different in patients with high RDI and low RDI in total phase and maintenance phase.

The prognosis of adult rhabdomyosarcoma remains poor, with approximately 30 % at 5-year survival [9–14, 16]. The reason for the poor outcome of adults remains unclear. Sultan et al. [9] reported the comparison of pediatric and adult rhabdomyosarcoma; they reported that the typical pediatric rhabdomyosarcoma variants (embryonal and alveolar subtypes) occurred less frequently in adult rhabdomyosarcoma and that the most common primary sites in adult were extremities and unfavorable sites and that radiation therapy was performed less frequently in adult rhabdomyosarcoma than in pediatric patients. In our study, adult rhabdomyosarcoma patients had lower RDIs in

VAC chemotherapy, especially in maintenance phase. The reason for the low RDI was not apparent, but we demonstrated that VAC chemotherapy for adult rhabdomyosarcoma patient may not be feasible as VAC chemotherapy was developed mainly targeting pediatric patients. We also suggested that none of the differences regarding RDIs of both vincristine and cyclophosphamide on PFS and OS were detected. However, in our previous data focusing on childhood RMS and adult RMS survival suggested significant differences in survival in localized tumor [17]. Although we could not observe significant differences in survival in metastatic tumors for both childhood RMS and adult RMS, controversy remains as to the standard treatment for patients with adult rhabdomyosarcoma. Recently, several types of trials for these patients have demonstrated to show additional benefit of adding active new agents to standard VAC chemotherapy, which failed to show survival benefit [18–20].

In IRS-V study, the dosage of cyclophosphamide was designed 1.2 g/m^2/cycle. High-dose therapy with stem cell transplantation for high-risk metastatic RMS did not

improve outcome significantly [21]. Accordingly, reduced dose of VAC chemotherapy for adults might not be inferior to standard VAC dose regarding survival.

This study has several limitations as of the nature of retrospective design and small sample size. More patients may be needed to detect the small differences regarding survival in low RDI patients and high RDI patients. Decision of administration of vincristine on day 8 and 15 may vary by physicians as evaluation of peripheral neuropathy by vincristine is not integrated. However, considering poor prognosis of adult RMS with highly toxic regimen of VAC, new strategy to treat this rare cohort must be developed urgently.

In summary, adult rhabdomyosarcoma is a rare malignancy with poor prognosis. The treatment strategy has been performed along with child rhabdomyosarcoma; however, the RDIs of vincristine and cyclophosphamide in the maintenance phase were significantly lower than that in children. Causes of low RDIs were generally myelosuppression, infection, and peripheral neurotoxicity in both groups. VAC chemotherapy for adults may not be feasible; thus, the prospective trial for adult rhabdomyosarcoma should be designed.

Acknowledgments We thank all the participants for supporting this study. Mrs. N. Nakamura supported for revising the manuscript.

A Case of Stage IV Neuroblastoma Treated with Aggressive Surgery Following Intensive Neoadjuvant Chemotherapy with Autologous Stem Cell Transplantation

Figure 1.

Figure 2.

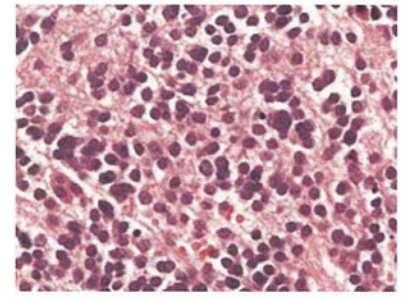

Figure 3.

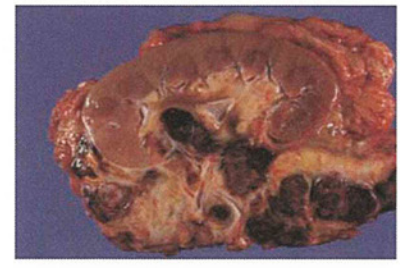

Figure 4.

A 16-year-old male complaining of recent body weight loss of 10 kg and supraclavicular lymph node swelling was referred to our hospital. Computed tomographic scan demonstrated a left retroperitoneal tumor (Fig. 1, arrow) and multiple enlarged lymph nodes along the aorta, mediastinum as well as in the supraclavicular area. The systemic spread of the disease was apparent on F^{18}-fluorodeoxyglucose-positron emission tomography including multiple bone metastases (Fig. 2). The urine level of vanillylmandelic acid and homovanillic acid and the serum level of neurospecific enolase were elevated to 107.8, 118.1 mg/g creatinine (Cr) and 140.9 ng/ml, respectively (reference range: 2.1–5.0, 2.2–5.8 mg/g Cr and $<$15 ng/ml, respectively). Histological analysis of the biopsied cervical lymph nodes confirmed the diagnosis of neuroblastoma, showing unfavorable histology (poorly differentiated) and no MYCN amplification (Fig. 3). According to the International Neuroblastoma Risk Group classification, the patient was categorized into the high-risk group due to the presence of metastatic disease and age $>$18 months. Because neoadjuvant chemotherapy with standard cisplatin-containing regimen was not effective, the patient underwent second-line ifosfamide-based chemotherapy followed by melphalan-containing high-dose chemotherapy with concomitant autologous peripheral blood stem cell transplantation. Then, he underwent surgical resection of abdominal tumor and lymph nodes (Fig. 4), followed by resection of mediastinal tumor and supraclavicular lymph nodes 50 days after the initial operation. Tumor beds and bone lesions were treated with post-operative radiation therapy. The patient is doing well without any signs of recurrence or treatment-related sequelae 8 months after completion of therapy.

Abstract
Background Outcomes in adult patients with rhabdomyosarcoma are poor, with a 5-year survival rate of approximately 30 %. The current study aimed to compare the clinical outcomes of adult and childhood rhabdomyosarcoma patients with local and metastatic disease and to examine the impact and timing of local therapy on metastasis.
Methods Clinicopathological features and patient outcomes were reviewed retrospectively for rhabdomyosarcoma patients receiving chemotherapy between 1981 and 2010 at our institution. Adults were defined as those aged 21 years or older.
Results Of the 98 patients identified, 36 were adults (median age, 29; range, 21–72) and 62 were children (median age, 11; range, 0.6–20). Median progression-free survival of localized and metastatic disease for children and adults was as follows: localized disease, 166.9 versus 22.4 months ($p = 0.005$), and metastatic disease, 13.3 versus 13.3 months ($p = 0.949$), respectively. Multivariate regression analysis revealed that older age (≥21 vs. <21) was a significant poor prognostic factor in localized disease. Conversely, age was not related to survival in metastatic disease. Receiving radiotherapy to the primary site was an independent factor indicating a better prognosis. An analysis of the optimal timing of local therapy was performed for 53 patients; however, its significance on survival could not be determined.
Conclusions Age was a negative prognostic factor in rhabdomyosarcoma patients with localized disease, but it did not affect the survival in metastatic disease. For metastatic disease, although local therapies may be effective for survival, the timing of such therapies should be determined individually.

Introduction

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in children, but it is far less common in adults (Ferrari et al. 2003). Improvements in multimodal treatment of RMS have improved survival in children from 25 to approximately 70 % over the past 40 years (Pappo et al. 1997; Raney et al. 2001; Breitfeld and Meyer 2005; Leaphart and Rodeberg 2007). In contrast, the prognosis for adult RMS remains poor, with a 5-year survival rate of approximately 30 % (Sultan et al. 2009; Ferrari et al. 2003;

La Quaglia et al. 1994; Little et al. 2002; Esnaola et al. 2001; Hawkins et al. 2001).

Metastatic RMS affects approximately 15 % of all children with RMS (Breneman et al. 2003). According to the risk categories identified by the Intergroup Rhabdomyosarcoma Study (IRS), low- and intermediate-risk patients have improved outcomes, with 96–97 % of low-risk patients achieving 5-year survival (Meza et al. 2006) and 79 % of intermediate-risk patients attaining 4-year survival (Arndt et al. 2009). However, survival for high-risk patients remains poor, with 34 % achieving 3-year survival (Oberlin et al. 2008) and 24 % achieving 5-year survival (Carli et al. 2004). Consequently, standard treatment for high-risk patients remains controversial (Klingebiel et al. 2008; Pappo et al. 2007; Lager et al. 2006).

The treatment strategy for RMS requires multidisciplinary therapy, including chemotherapy, surgery, and radiation therapy. Vincristine and *d*-actinomycin, with or without cyclophosphamide (VAC) regimens, are considered the standard option for RMS (Maurer et al. 1988, 1993; Crist et al. 1995, 2001; Meza et al. 2006; Arndt et al. 2009), with wide surgical resection of tumor and postoperative radiation therapy required for local control of localized RMS (La et al. 2011; Rodeberg et al. 2011; Schuck et al. 2004). The timing of radiation therapy is critical: for localized RMS, radiation is appropriate to start during weeks 9–12, and for parameningeal RMS with intracranial extension, local radiation treatment should begin during the first 1–2 weeks of chemotherapy (Michalski et al. 2004; Raney et al. 2002). However, the impact and optimal timing of local therapy for metastatic disease is unknown. Therefore, the purpose of the current study was to compare the clinical outcomes of local or metastatic adult and childhood RMS and to examine the impact and timing of local therapies on metastatic disease.

Patients and methods

Patients

All patients included in this analysis met the following criteria: histologically diagnosed with RMS, treated at the National Cancer Center Hospital in Tokyo between 1981 and 2010, and received VAC or VAC-like chemotherapy. Medical records were then retrospectively reviewed to obtain the following information: date of birth, gender, date of diagnosis, primary tumor site, histopathology, initial tumor size, presence of central nervous system (CNS) invasion, clinical stage, group category as defined by the IRS (Breitfeld and Meyer 2005), date of treatment initiation, chemotherapy regimen, best response, chemotherapy administration schedule, date of radiotherapy, date of surgery, date of progression, date of last follow-up, and survival status.

Treatment

The VAC regimen after the year of 2000 consisted of vincristine at a dose of 1.5 mg/m^2 (up to 2 mg/body), given intravenously on days 1, 8, and 15; cyclophosphamide at a dose of 2.2 g/m^2, given intravenously on day 1; and *d*-actinomycin at a dose of 1.5 mg/m^2 (up to 2.5 mg/body), given intravenously on day 1. The treatment course was repeated according to IRS-IV or Children's Oncology Group (COG) Study (D9803) protocols (Arndt et al. 2009). Before the year of 2000, the VAC-like regimen includes the following regimens: vincristine, *d*-actinomycin, and either ifosfamide, etoposide, or doxorubicin. The treatment course was administered according to IRS-II or III protocols.

Local therapy includes surgery, radiation therapy, or both. Surgical resection defined in this manuscript includes only total gross resection. Microscopic complete resection (Group I) was confirmed microscopically later on. Radiation therapy was delivered to each primary tumor site and regional lymph nodes where applicable. The total dose ranged from 30 to 56.3 Gy, with a median dose of 45 Gy.

Definitions of terms

We defined adults as patients aged 21 years or more, and considered the remaining patients to be children. The induction phase was defined as the first six cycles of the VAC/VAC-like regimen, and the maintenance phase was defined as the later cycles following the induction phase. Response to chemotherapy was compared with baseline status. A complete response (CR) was defined as the disappearance of tumors with no evidence of disease. A partial response (PR) was a 50 % or greater decrease in the sum of tumor diameters. Stable disease (SD) was a less than 50 % decrease in the sum of tumor diameters. Progressive disease (PD) was defined as a 25 % or greater increase in the sum of tumor diameters and/or the appearance of new lesions.

Surgery or radiation therapy in this study means resection or radiation therapy to the primary site during primary treatment, respectively. Resection or radiation therapy to a relapsed site or metastatic site is not included in this category; likewise, biopsy only is not included in this definition.

Statistical analyses

Progression-free survival (PFS) was defined as the time from the date of initial chemotherapy to the date when

local recurrences or distant metastases were recognized. Overall survival (OS) was defined as the time from the date of initial chemotherapy to the date of death due to any cause. Patients who survived were treated as censored observations on the last day of follow-up. PFS and OS were estimated using the Kaplan–Meier method, and survival curves were compared using the log-rank test. Multivariate Cox regression analysis was used to estimate the hazard ratios and 95 % confidence intervals (CI). A two-sided $p < 0.05$ was considered statistically significant. All statistical analyses were performed using SAS (version 9.1.3; SAS Institute Inc., Cary, NC, USA).

Results

Patient characteristics

We identified 98 patients who met the eligibility criteria. The distributions of clinical and pathologic characteristics of patients are listed in Tables 1 and 2. There were 36 adults (age: median, 29; range 21–72) and 62 children (age: median, 11; range, 0.6–20). Seventy-three patients had localized disease (22 adults and 51 children) , while 25 patients had metastatic disease (14 adults and 11 children). The most common histology was embryonal in localized disease (56.2 %) and alveolar in metastatic disease (68.0 %). Botryoid was found in only one patient. Common primary sites in localized disease were parameningeal (38.4 %), head and neck (21.9 %), and extremity (15.1 %), while common primary sites in metastatic disease sites were parameningeal (32.0 %), extremity (28.0 %), and other (24.0 %) (Table 3). The most common metastatic

sites were bone ($n = 17$), bone marrow ($n = 7$), and lung ($n = 6$). Eleven patients had metastases to multiple sites.

Thirty-one patients (31.6 %) underwent surgical resection at RMS diagnosis. Ten patients were classified as IRSG Group I, 7 as Group II, and 14 as Groups III/IV. Surgery (primary tumor resection at diagnosis or second-look surgery) was performed in 43 patients (58.9 %) with localized disease and in 5 patients (20.0 %) with metastatic disease. We identified 59 patients (60.2 %) who had received VAC regimens and 39 patients (39.8 %) who had received VAC-like regimens. Radiation therapy was performed in 52 patients (71.2 %) with localized disease and in 18 patients (72.0 %) with metastatic disease during the course of treatment.

Patient outcomes in adults and children

The best responses to chemotherapy were as follows: among those with localized disease, 65 patients (89.0 %) achieved CR/PR, 5 patients (6.9 %) achieved SD/PD, and the data are not available for 3 patients (4.1 %); among patients with metastatic disease, 22 patients (88.0 %) achieved CR/PR and 3 patients (12.0 %) achieved SD/PD ($p = 1.000$). The overall median follow-up period was 37 months (range, 0–263 months); 37 months in metastatic disease (range, 0–213 months); and 43 months in localized disease (range, 0–263 months). At the time of analysis, 50 patients (51.0 %) experienced recurrence, and 41 of these patients (41.8 %) later died. Sites of first recurrence/progression were locoregional in 26 patients and distant metastases in 24 patients. Seven patients in whom the sites of first recurrence/progression were locoregional achieved CR and were still alive following second-line treatment.

Adult patients with localized disease had a significantly greater probability of poor outcome compared with children. The median PFS times for localized and metastatic disease for children and adults were as follows: localized disease, 166.9 versus 22.4 months ($p = 0.005$) (Fig. 1a), and metastatic disease, 13.3 versus 13.3 months ($p = 0.949$) (Fig. 1b), respectively. Median OS times were not statistically different in patients with metastatic disease for both adults and children.

Analyses of prognostic factors in localized and metastatic disease

To determine the independent predictors of survival, we used a multivariate Cox regression model. The results of multivariate analysis for PFS and OS in localized and metastatic disease are shown in Tables 4 and 5. According to Table 4, age (<21 vs. ≥21) was the only statistically significant negative predictor of PFS for patients with localized disease ($p = 0.018$). In contrast, for metastatic disease, age was not significantly different with respect to

PFS and OS. Radiotherapy was the only significant factor in improved PFS or OS in metastatic disease.

Local therapy for metastatic disease

Of 25 patients with metastatic disease, 21 patients (84.0 %) received local therapy as part of their primary treatment that included radiotherapy ($n = 16$), surgery and radiotherapy ($n = 3$), and surgery ($n = 2$). Sixteen of these 21 patients (76.2 %) experienced relapse at the following sites: distant metastatic site ($n = 11$) and primary site progression ($n = 5$). Among four patients with metastatic disease who did not receive local therapy, three patients relapsed: two experienced local relapse and one relapsed at a distant metastatic site. In the 25 patients with metastatic disease, median PFS times in patients with or without local therapy (surgery and/or radiotherapy) were 13.4 versus 7.0 months ($p < 0.001$) (Fig. 2a), respectively, and median OS times were 36.1 versus 7.6 months ($p < 0.001$), respectively (Fig. 2b).

Timing of local therapy

We further sought information about the optimal timing of local therapy in 53 patients who received local therapy (both radiotherapy and surgery) during their course of treatment (localized disease, $n = 38$; metastatic disease, $n = 15$). PFS and OS were not significantly different

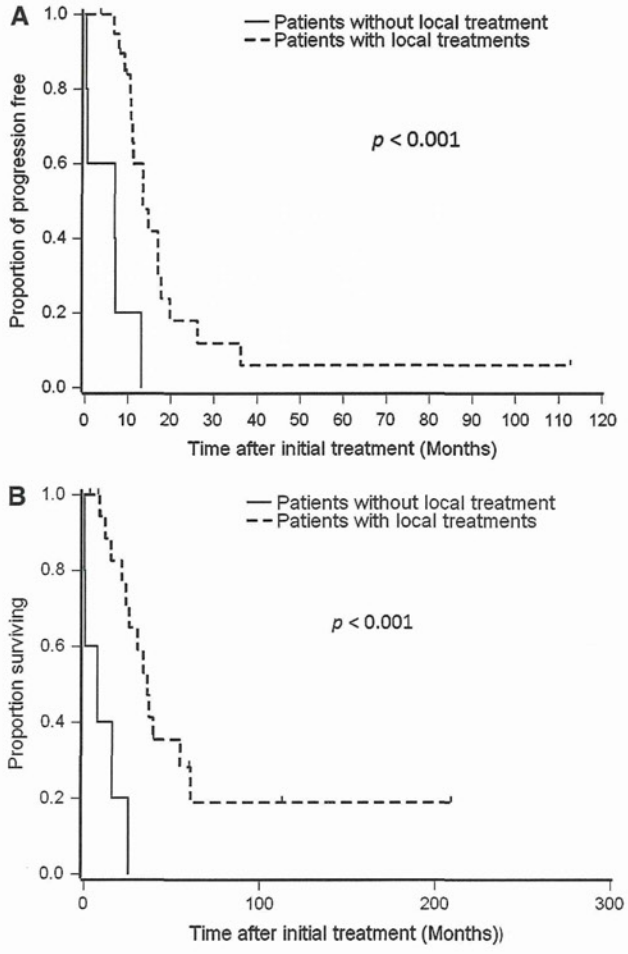

Fig. 2 Kaplan–Meier curve of progression-free survival (**a**) and overall survival (**b**) in patients with metastatic disease with local therapy (*dashed line*) and without local therapy (*solid line*)

between patients who received local therapy within or after 18 weeks of starting initial treatment (see Table 6 for our multivariance analysis of OS). In the 38 patients with localized disease, median PFS was 134.7 months in patients who received radiotherapy in the induction phase and 101.6 months in patients who received it during the maintenance phase ($p = 0.921$); median OS was similar for patients during both phases ($p = 0.277$). Median PFS and OS times were also similar in patients who received surgery either in the induction phase or in the maintenance phase ($p = 0.304$ for PFS and $p = 0.502$ for OS).

In the 15 patients with metastatic disease, the median PFS in patients who received radiotherapy was similar for both phases (induction, 18.4 months; maintenance, 13.3 months, $p = 0.177$); however, median OS was significantly longer for the patients receiving radiotherapy in the induction phase than for those receiving radiotherapy in the maintenance phase (60.7 and 25.7 months, respectively, $p = 0.048$). Median PFS and OS were similar in patients who received surgery in either the induction or maintenance phase ($p = 0.304$ for PFS and $p = 0.214$ for OS).

Discussion

In this study, we evaluated the clinical outcomes of adults and children with RMS who received VAC/VAC-like chemotherapy as their initial treatment. This study resulted in two main findings. First, we showed that age was an independent negative prognostic factor for PFS in RMS with localized disease, but it was not associated with survival in metastatic disease. Second, local therapy to the

primary tumor site during the treatment course may be necessary for metastatic RMS, as the patients who received local therapies showed significantly longer survival than those who did not. Although our findings suggest that patients with metastatic RMS should be treated at an early stage with local radiotherapy to improve OS, this aspect of our results requires more research; thus, the timing of local therapy should be individually determined depending on patient conditions.

Several studies have reported that age is associated with poor survival in patients with RMS. Sultan et al. reported on the prognosis of pediatric (age $\leqq$ 19 years) and adult (age > 19 years) RMS patients, and their findings suggested that the 5-year survival rate was significantly poorer in adults compared to that in children (5-year OS, 27 and 61 %, respectively; $p < 0.0001$) (Sultan et al. 2009). Another study clarified that the outcomes of patients with intermediate-risk RMS varied depending on age (Meza et al. 2006). Oberlin et al. (2008) also reported on the prognosis of metastatic RMS, and their data suggested that the 3-year event-free survival rate was significantly poorer in RMS patients <1 year and >9 years of age compared to that in RMS patients aged 1–9 years ($p < 0.001$). In our study, age was a negative prognostic factor of PFS in RMS with localized disease, but outcomes for metastatic disease were not different between adults and children. Previous studies have mostly focused on age in children, but our study reported different prognoses for adults and children in both localized and metastatic disease. Therefore, our results would be expected to be different than those of Oberlin et al. (2008). The poor prognosis in adult metastatic RMS may depend on the tumor biology and drug delivery.

Histopathological classification of adult RMS is somewhat difficult to categorize conventional subtypes. Although our data include alveolar subtype most, pleomorphic and spindle subtypes in part may be included in the heterogeneous tumor and these subtypes are suggested poor prognosis (Mentzel, 2000 #3204). For the drug delivery, unpublished data in our institute suggest that the dose intensity of vincristine and cyclosporine is lower in adult when compared to children as hematological toxicities and neurotoxicity are severe. These data suggest that categorizing adult RMS and its treatment may be necessary to be developed independently to that of child RMS.

Radiation therapy and surgery are important for local tumor control and survival in the treatment of RMS. However, the optimal timing of radiation therapy is unclear. IRSG and COG protocols incorporate radiation therapy scheduled at weeks 9 or 12 after the induction of initial chemotherapy (Crist et al. 2001; Arndt et al. 2009). Minn et al. (2010) analyzed the risk of early treatment failure in intermediate-risk RMS, and the majority of patients with early progression experienced local failure. Earlier radiation therapy may improve outcomes by the prevention of early local progression, and the current COG study (ARST0531, http://www.clinicaltrials.gov) plans to perform radiation therapy at week 4 for intermediate-risk RMS. Although there has been no randomized trial to compare the timing of local therapy in RMS, early initiation of local treatment would seem to be preferable. In our study, local therapy was effective in improving survival even in metastatic disease. We could find the efficacy of radiotherapy in metastatic patients but not for surgery probably because of the shortage of patients number included. However, except for local radiotherapy in patients with metastatic disease, the timing of local therapy had no significantly different effect on outcomes in patients who received local therapy during the induction phase versus the maintenance phase. The threshold we used for dichotomization (within 18 weeks or later than 18 weeks after initial treatment onset) may have been a factor in our inability to detect a significant difference in outcomes. This result implies that the timing of local therapy for metastatic disease, whether radiotherapy or surgery, may be varied depending on the individual patient's characteristics, that is, the radiotherapeutic field or the operability of the patient's local site.

Several limitations to our study should be mentioned. Our analysis was limited by its retrospective design and small sample size. Patients receiving VAC-like chemotherapy had undergone chemotherapy during the period prior to 2000, and the dose intensity of chemotherapy varied by protocol. The dose of irradiation and radiation methods also varied. Further, the patients who received local therapy might have been in better general condition or had a smaller primary tumor, which could be included in one radiation field, compared with those who did not. To reduce these biases, we compared the baseline characteristics of each group and demonstrated their similarity. However, adult RMS is a rare cancer; thus, our results should contribute to further advances in this field of oncology.

In conclusion, we showed that age was a negative prognostic factor for PFS and OS in RMS patients with localized disease, but age was not associated with survival in metastatic disease. For metastatic disease, local therapy may have a beneficial effect on survival, but the optimal timing of local therapy is unclear and should be determined individually. Future clinical trials for metastatic RMS should focus on the timing of local therapy, and evaluation of treatment strategies limited to adult RMS patients is warranted.

Conflict of interest None.
