Obesity has become more prevalent in most developed countries over the past few decades, and is increasingly recognized as a major risk factor for several common types of cancer¹. As the worldwide obesity epidemic has shown no signs of abating², better understanding of the mechanisms underlying obesity-associated cancer is urgently needed. Although several events were proposed to be involved in obesity-associated cancer^{1,3}, the exact molecular mechanisms that integrate these events have remained largely unclear. Here we show that senescence-associated secretory phenotype (SASP)^{4,5} has crucial roles in promoting obesity-associated hepatocellular carcinoma (HCC) development in mice. Dietary or genetic obesity induces alterations of gut microbiota, thereby increasing the levels of deoxycholic acid (DCA), a gut bacterial metabolite known to cause DNA damage⁶. The enterohepatic circulation of DCA provokes SASP phenotype in hepatic stellate cells (HSCs)⁷, which in turn secretes various inflammatory and tumour-promoting factors in the liver, thus facilitating HCC development in mice after exposure to chemical carcinogen. Notably, blocking DCA production or reducing gut bacteria efficiently prevents HCC development in obese mice. Similar results were also observed in mice lacking an SASP inducer⁸ or depleted of senescent HSCs, indicating that the DCA-SASP axis in HSCs has key roles in obesity-associated HCC development. Moreover, signs of SASP were also observed in the HSCs in the area of HCC arising in patients with non-alcoholic steatohepatitis³, indicating that a similar pathway may contribute to at least certain aspects of obesity-associated HCC development in humans as well. These findings provide valuable new insights into the development of obesity-associated cancer and open up new possibilities for its control.

Cellular senescence is a process occurring in normal cells in response to telomere erosion or oncogene activation, acting through checkpoint activation and stable cell-cycle arrest as a barrier to tumorigenesis^{9,10}. Recent studies, however, reveal that senescent cells also develop a secretory profile composed mainly of inflammatory cytokines, chemokines and proteases, a typical signature termed the senescence-associated secretory phenotype (SASP)⁴ or the senescence messaging secretome (SMS)⁵, hereafter referred to as SASP. Some of the SASP factors have cell-autonomous activities that reinforce senescence cell-cycle arrest⁵ and/or promote clearance of senescent cells^{11,12}, but other SASP factors have cell non-autonomous functions associated with inflammation and tumorigenesis promotion⁴, indicating that SASP contributes positively and negatively to cancer development, depending on the biological context^{4,5}. Because some of the SASP factors, such as IL-6 and PAI-1^{4,5}, are known to increase cancer risk in obesity^{1,13}, we propose that SASP may contribute to obesity-associated cancer.

To explore this possibility, we first set up a system to examine the impact of dietary obesity on tumorigenesis, using wild-type C57BL/6

mice. However, we were unable to detect a statistically significant difference in cancer development between obese mice fed a high-fat diet (HFD) and lean mice fed a normal diet (data not shown), implying that a certain level of oncogenic stimuli might be required for obesity-associated cancer, especially in wild-type mice maintained in a specific pathogen free (SPF) environment. Because the Ras-pathway is frequently activated in human cancers, including hepatocellular carcinoma (HCC)¹⁴, we decided to use a treatment with DMBA (7,12-dimethylbenz(a)anthracene, a chemical carcinogen that causes an oncogenic Ras mutation) at the neonatal stage, a protocol known to generate a variety of tumours throughout the body¹⁵. In this setting, we also took advantage of using p21-*p*-luc mice, in which the expression of the p21^{Waf1/Cip1} gene (a senescence inducer, also known as *Cdkn1a*) can be monitored noninvasively using a bioluminescence imaging (BLI) technique¹⁶. The neonatal p21-*p*-luc mice were therefore treated with a single application of DMBA, followed by feeding either HFD or normal diet for 30 weeks (Fig. 1a). Interestingly, a marked increase of the bioluminescent signal was observed in the abdomen of the obese mice, and it originated mainly from liver cancer (Supplementary Fig. 1). Notably, all HFD-fed mice developed HCC, whereas only 5% of -mice fed normal diet developed malignant tumours in lung, but not liver (Fig. 1b–e and Supplementary Fig. 2). Importantly, moreover, similar HCC development was also observed when genetically obese (*ob/ob*, also known as *Lep^{ob/ob}*) mice were treated with DMBA at the neonatal stage (Supplementary Fig. 3a–d), indicating that obesity, but not the HFD, promotes HCC development.

Because the induction of p21^{Waf1/Cip1} expression was observed in liver, particularly in the area of liver cancer (Supplementary Fig. 1c), we speculated that senescent cells might be present in the vicinity of cancerous hepatocytes. Indeed, p21^{Waf1/Cip1} expression was observed only in activated hepatic stellate cells (HSCs), which express α -smooth muscle actin (α -SMA) and desmin⁷ (Fig. 1f). Furthermore, a number of other senescence markers^{9,10}, such as p16^{INK4a} expression, signs of DNA damage (53BP1 foci and γ H2AX foci) and inhibited cell proliferation (the absence of bromodeoxyuridine incorporation and Ki-67 expression), were also observed in activated HSCs despite absence of oncogenic *ras* mutation (Fig. 1f and Supplementary Figs 3e and 4). Interestingly, moreover, increased expression of IL-6, Gro- α , CXCL9 (major components of SASP)^{4,5}, but not HGF (a differentiation marker)⁷, was observed in activated HSCs, but not in other types of liver cells (Fig. 1f and Supplementary Figs 3e and 5), indicating that these activated HSCs are senescing and may promote obesity-associated HCC development via SASP. It should be noted that, unlike the study using carbon tetrachloride (CCl₄)¹¹, fibrosis was not apparent in HFD-fed mice (Supplementary Fig. 6), precluding the possibility that the appearance of senescent HSCs was a by-product of liver fibrosis.

To ascertain the role of SASP in obesity-associated HCC development, we next sought evidence that the blockage of SASP can reduce obesity-associated HCC development. Although we were unable to detect the expression of IL-1 α (an upstream regulator of SASP induction)⁸ in HSCs, significant induction of IL-1 β (a functional homologue of IL-1 α) and its activator, caspase-1 (an essential component of the inflammasome), was observed in senescent HSCs (Fig. 2a–c). Moreover, the addition of recombinant IL-1 β caused the dose-dependent induction of *Il-6* and *Gro- α* (also known as *Cxcl1*) gene expression in cultured primary murine HSCs (Supplementary Fig. 7a), indicating that inflammasome activation and subsequent IL-1 β maturation can act as an upstream regulator of SASP induction in HSCs. Indeed, the levels of SASP factor expression in activated HSCs were substantially diminished in mice lacking the *Il-1 β* gene (*Il-1 β* ^{-/-} mice, also known as *Il1b*^{-/-}) (Fig. 2c), and the numbers and sizes of the liver tumours that developed in *Il-1 β* ^{-/-} mice were strikingly reduced, as compared with wild-type mice (Fig. 2d, e), although the degree of steatohepatitis was not attenuated (Supplementary Fig. 8a, b). It should be noted, however, that other senescence markers, such as 53BP1 foci, p21^{Waf1/Cip1} expression and inhibited cell proliferation, were still observed in the activated HSCs of *Il-1 β* ^{-/-} mice (Fig. 2c and Supplementary Fig. 8c). These results are somewhat consistent with a recent observation that the

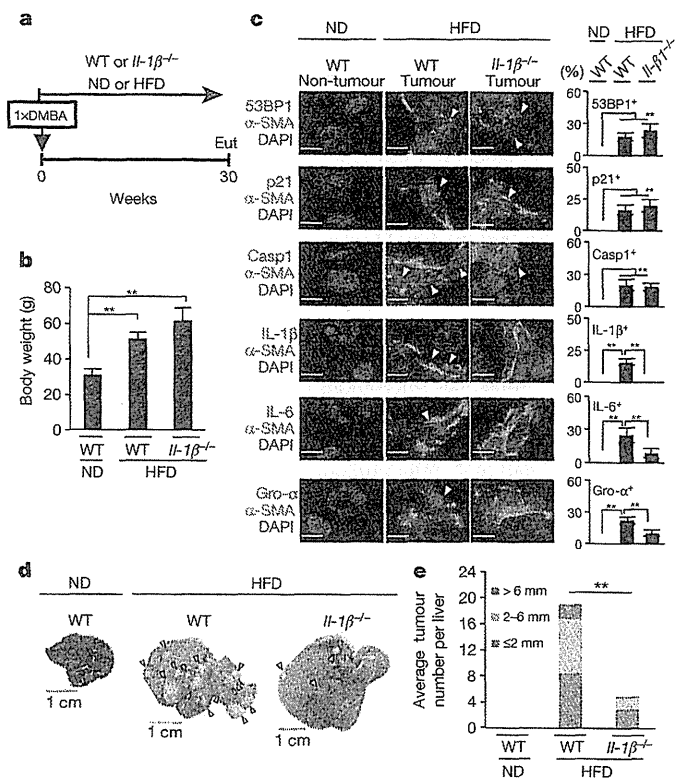

Figure 2 | IL-1 β deficiency alleviates obesity-induced HCC development. a, Timeline of the experimental procedure (wild type (WT), $n = 19$; *Il-1 β* ^{-/-}, $n = 9$). b, The average body weights at the age of 30 weeks. c, Immunofluorescence analysis of liver sections. expression of p21^{Waf1/Cip1} can induce senescence cell-cycle arrest without SASP induction¹⁷, suggesting that SASP, but not senescence cell-cycle arrest, promotes obesity-associated HCC development.

To further verify this idea, we next attempted to deplete senescent HSCs from obese wild-type mice treated with DMBA at the neonatal stage. As reported previously¹⁸, an intravenous injection of liposomes carrying small interfering RNA (siRNA) against HSP47 substantially reduced the abundance of activated HSCs, coinciding with a significant reduction of HCC development (Supplementary Fig. 9a–f). Note that this was not accompanied by an attenuation of steatohepatitis (Supplementary Fig. 9g, h). These results, along with the data from *Il-1 β* ^{-/-} mice (Fig. 2), strongly indicate that senescent HSCs have enhancing roles in HCC development via SASP, at least in the neonatal DMBA plus obesity-induced HCC model. It is also noteworthy that neither the deletion of the *Il-1 β* gene nor the depletion of senescent HSCs caused appreciable weight loss (Fig. 2b and Supplementary Fig. 9c), implying that there may be an indirect link between obesity and HCC development, at least in this experimental setting. These observations then raised the question of how obesity provokes SASP in HSCs.

Emerging evidence has indicated that alterations of intestinal microbiota are associated with obesity¹⁹. Furthermore, the activation of toll-like receptor (TLR) 4 by lipopolysaccharide (LPS) from intestinal Gram-negative bacteria has been shown to promote HCC development, in an HCC model using DEN (diethyl nitrosamine) plus CCl₄ treatment²⁰. We thus explored the possibility that intestinal bacteria have key roles in obesity-associated HCC development. Indeed, a

treatment with a well-established oral antibiotic cocktail (4Abx), which reduces the number of commensal intestinal bacteria²⁰, caused a marked reduction of HCC development, accompanied by a marked decrease in senescent HSCs in the neonatal DMBA plus obesity-induced HCC model (Fig. 3 and Supplementary Fig. 3). As reported²⁰, 4Abx treatment resulted in not only a > 99.5% reduction of the presence of bacterial 16S ribosomal RNA gene in faeces, but also an enlargement of caecum commonly observed in germ-free mice (Fig. 3b and data not shown). Unexpectedly, however, a slight increase, rather than decrease, in HCC development was observed in mice lacking the *Thr4* gene (*Thr4*^{-/-}) (Supplementary Fig. 10), indicating that LPS from Gram-negative bacteria is unlikely to promote HCC development in this setting. Indeed, meta 16S rRNA gene sequencing analysis of the intestinal microbiota revealed that the percentage of Gram-positive bacterial strains indigenous to the human and rodent intestinal tracts⁶ was dramatically increased with a HFD (Fig. 4a). Moreover, a treatment with vancomycin (VCM), an antibiotic that preferentially targets Gram-positive bacteria, alone was sufficient to block HCC development and the appearance of senescent HSCs (Figs 3d–f, 4a and Supplementary Fig. 3). These results lead us to propose that the obesity-associated increase of Gram-positive bacteria may promote HCC development, presumably through the enterohepatic circulation of gut bacterial metabolites or toxins.

To substantiate this idea, the serum metabolites of HFD- and normal-diet-fed mice were analysed by liquid chromatography mass spectrometry (LC-MS). Interestingly, the level of deoxycholic acid (DCA), a secondary bile acid produced solely by the 7 α -dehydroxylation of

primary bile acids carried out by gut bacteria such as strains belonging to *Clostridium* cluster XI and XIVa⁶ (VCM-sensitive Gram-positive bacteria), was substantially increased by the HFD feeding, and was reduced by antibiotic treatments (Figs 3a and 4b). Note that DCA is known to cause DNA damage through reactive oxygen species production²¹ and DNA damage is a critical inducer of SASP^{4,22}. Moreover, in addition to colon carcinogenesis²³, DCA has been shown to enhance liver carcinogenesis²⁴. These notions prompted us to examine if DCA has key roles in obesity-associated HCC development. To this end, we attempted to lower the levels of DCA, by either decreasing the 7 α -dehydroxylation activity with difructose anhydride III (DFA III)²⁵ or stimulating bile acid secretion with ursodeoxycholic acid (UDCA)²⁶. Notably, lowering the DCA concentration substantially reduced HCC development, accompanied by a marked decrease in senescent HSCs in obese mice treated with DMBA at the neonatal stage (Fig. 4b and

Supplementary Figs 11 and 12). In a reciprocal set of experiments, we also assessed whether DCA-feeding enhances HCC development in mice treated with DMBA at the neonatal stage (Fig. 4c). Intriguingly, although DCA feeding alone was insufficient to enhance HCC development in lean mice fed a normal diet at 30 weeks (data not shown), a significant enhancement of HCC development (Fig. 4c–f), accompanied by the appearance of senescence cell-cycle arrest and SASP in HSCs (Fig. 4g), was observed when HFD-fed mice treated with 4Abx were fed DCA for 17 weeks.

Notably, operational taxonomic unit (OTU)-based bacterial diversity analysis (Fig. 4a), in conjunction with a quantitative PCR analysis (Supplementary Fig. 13), revealed that the population of cluster XI of the genus *Clostridium* was strikingly increased in HFD-fed mice. Interestingly, phylogenetic analysis of the bacterial OTUs revealed that the population of *Clostridium* cluster XI is composed of a single bacterial taxon (OTU-1105) close to the DCA-producing strain *Clostridium sordellii*, and represents more than 12% of the faecal bacteria in HFD-fed mice (Supplementary Fig. 14). Concordantly, moreover, the abundance of the *bail* gene, a gene involved in bile acid 7 α -dehydroxylation²⁷, was remarkably increased in faeces of mice fed HFD and was reduced by VCM treatment (Fig. 4h). On the other hand, a bacterial taxon (OTU-154) close to other DCA producing strains belonging to *Clostridium* cluster XIVa (*Clostridium hylemonae* and *Clostridium scindens*) represents only 0.5% of the total faecal bacteria in HFD-fed mice (Supplementary Fig. 14). Thus, although other bacteria may also be involved here, the simplest explanation for our data is that OTU-1105 belonging to *Clostridium* cluster XI contribute to an increase in the DCA level at least to some extent in HFD-fed mice.

Finally, to further support and extend our murine data to human biology, we tested whether IL-1 β treatment can induce SASP in cultured primary human HSCs. As in murine HSCs, the addition of recombinant IL-1 β caused the induction of *Il-6* and *Il-8* (a functional homologue of murine *Gro- α*) gene expression in cultured primary human HSCs (Supplementary Fig. 7b). Importantly, moreover, signs of cellular senescence and SASP were also observed in the HSCs without serious fibrosis in the area of HCC arising in patients with non-alcoholic steatohepatitis (NASH)³ (8 out of 26) (Supplementary Fig. 15). This is somewhat consistent with previous observations that replicative senescence of cultured human HSCs is accompanied by a pronounced inflammatory but less fibrogenic phenotype²⁸ and a certain percentage of NASH-associated HCC arose from the non-cirrhotic liver²⁹. Unlike rodents, the human liver cannot 7 α -hydroxylate DCA, forming cholic acid⁶. Hence, DCA can accumulate to very high levels (>50%) in the bile acid pool of humans⁶. These data, together with the previous observation that high fat consumption resulted in higher faecal DCA concentrations in healthy male volunteers (ages 20–60)³⁰, suggest that DCA-induced senescent HSCs may contribute to at least certain aspects of obesity-associated HCC development via SASP in humans as well.

It should be noted that although many of the perturbations, for example, the *Il-1 β* knockout, antibiotics treatment and lower DCA levels, significantly prevent HCC development, residual HCCs were still observed with these perturbations (Figs 2e and 3e and Supplementary Figs 11c and 12c). These results, in conjunction with the observation that DCA-feeding alone was insufficient to enhance HCC development in lean mice fed a normal diet until at least 30 weeks (data not shown), imply that an additional factor associated with obesity may exist to promote obesity-associated HCC development. Nevertheless, combining published data^{14,19,21,24,30} with our findings, it is clear that the increased levels of DCA produced by gut bacteria play key roles in the promotion of obesity-associated HCC development via provoking SASP in HSCs, at least in the neonatal DMBA plus obesity-induced HCC model (Supplementary Fig. 16). A greater understanding of the molecular mechanisms linking gut microbial metabolite to SASP will therefore provide valuable new insights into how to bypass this undesirable side effect of cellular senescence.

METHODS SUMMARY

Chemically-induced carcinogenesis. DMBA treatments¹⁵ consisted of a single application of 50 μ l of a solution 0.5% DMBA (7,12-dimethylbenz [a]anthracene, Sigma) in acetone to the dorsal surface on postnatal day 4–5. Mother mice with pups were then fed either normal diet or HFD until weaning. At the age of 4 weeks old, pups were weaned and continuously fed either normal diet or HFD until euthanized.

Bacterial 16S rRNA amplicon sequencing and analysis. Bacterial genomic DNA was isolated from mice faeces, amplified for V1–V4 hypervariable regions of the 16S rRNA gene, and used for pyrosequencing analysis.

METHODS

Mice and diet. The *p21-p-luc* mice (CD1)¹⁶ were backcrossed with C57BL/6 mice for eight generations. The leptin-deficient (*ob/ob*) mice (C57BL/6) were purchased from Charles River Laboratories Japan, Inc. *Thr4^{-/-}* mice (C57BL/6) were purchased from Oriental Bioservices. *IL-1β^{-/-}* mice (C57BL/6) were provided by Y. Iwakura³¹. Male mice were used for all the experiments in this study. The mice were maintained under specific pathogen-free (SPF) conditions, on a 12-h light-dark cycle, and fed normal diet (CE-2 from CLEA Japan Inc., composed of 12 kcal% fat, 29 kcal% protein, 59 kcal% carbohydrates) or high-fat diet (HFD, D12492 from Research Diets Inc., composed of 60 kcal% fat, 20 kcal% protein, 20 kcal% carbohydrates) *ad libitum*. Mice with more than 45 g weight at the age of 30 weeks old were used as obese mice for all the experiments. We measured the amount of food our mice eat and found that a 50 g HFD mouse eats 3.44 g food a day. This equates to 1.2 g of fat per day or 24 g per kg. According to the Reagan-Shaw equation³² (human equivalent dose (mg kg⁻¹) = mouse dose (mg kg⁻¹) × mouse *K_m* factor ÷ human *K_m* factor; where the mouse and human *K_m* factors are 3 and 37, respectively), this is equivalent to a 70 kg human eating 136 g of fat a day. The sample size used in this study was determined based on the expense of data collection, and the need to have sufficient statistical power. Randomization and blinding were not used in this study. All animal experiments were cared for by protocols approved by the Committee for the Use and Care of Experimental Animals of the Japanese Foundation for Cancer Research (JFCR).

Chemically induced carcinogenesis. DMBA treatments¹⁵ consisted of a single application of 50 μl of a solution 0.5% DMBA (7,12-dimethylbenz(a)anthracene, Sigma) in acetone to the dorsal surface on postnatal day 4–5. After this application, mother mice with pups were fed normal diet or HFD. At the age of 4 weeks old, pups were weaned and continuously fed either normal diet or HFD until euthanized. Evaluation of tumour number and size was determined by counting the number of visible tumours and measuring the size of the tumour.

Bioluminescence imaging. Bioluminescence imaging was performed as previously described^{16,33}. In brief, for the detection of luciferase expression, mice were anesthetized, injected intraperitoneally with D-luciferin sodium salt (75 mg kg⁻¹) 5 min before beginning photon recording. Mice were placed in the light-tight chamber and a grey-scale image of the mice was first recorded with dimmed light followed by acquisition of luminescence image using a cooled charged-coupled device (CCD) camera (PIXIS 1024B; Princeton Instruments). The signal-to-noise ratio was increased by 2 × 2 binning and 5 min exposure. For colocalization of the luminescent photon emission on the animal body, grey scale and pseudo-colour images were merged by using IMAGE-PRO PLUS (Media Cybernetics).

Antibiotics treatment. Antibiotics treatment was performed as previously described²⁰ using a combination of four antibiotics (4Abx) of ampicillin (1 g l⁻¹), neomycin (1 g l⁻¹), metronidazole (1 g l⁻¹) and vancomycin (500 mg l⁻¹), or vancomycin (500 mg l⁻¹) alone (VCM) in drinking water at the age of 13 weeks old until killed.

Histology and immunofluorescence analysis. Haematoxylin and eosin staining and immunofluorescence analysis were performed as previously described¹⁶. The primary antibodies used for mouse samples were as follows: α-SMA (Sigma A5228), desmin (abcam ab15200), p21 (abcam ab2961), p16 (Santa Cruz sc1207), 53BP1 (Santa Cruz sc22760), γ-H2AX (CST 9718), IL-6 (abcam ab6672), Gro-α (abcam ab17882), Ki-67 (Thermo RM9106), bromodeoxyuridine (abcam ab6326), caspase-1 (Millipore 06-503), IL-1β (R&D systems AF-401-NA), HSP47 (Santa Cruz sc8352), CXCL9 (abcam ab137792), F4/80 (Invitrogen BM8) and CD45 (Millipore 05-1416). The primary antibodies used for human samples were as follows: α-SMA (Dako M0851), γ-H2AX (CST 9718), p16 (Santa Cruz sc56330), p21 (CST #2947), IL-6 (abcam ab6672), IL-8 (abcam ab18672), 53BP1 (Santa Cruz sc22760) and caspase-1 (Millipore 06-503).

Quantitative PCR. Total RNA was extracted from mouse tissues using TRIzol reagent (Life technologies) and reverse transcription and quantitative PCR were performed as previously described². Primers used were as follows: human *GAPDH*, 5'-CAACTACATGGTTTACATGTTCC-3' (forward) and 5'-GCCAGTGGACTCCACGAC-3' (reverse), mouse *Gapdh*, 5'-CAACTACATGGTCTACATGTTCC-3' (forward) and 5'-CACCAGTAGACTCCACGAC-3' (reverse), human *IL-6*, 5'-CTGACGGCATCTCAGCCCTGA-3' (forward) and 5'-CTGCCAGTGCCTCTTTGCTGCTTT-3' (reverse), mouse *Il-6*, 5'-TGATTGTATGAACAACGATGATGC-3' (forward) and 5'-GGACTTGGCTTTGTCTTTCTTGT-3' (reverse), human *IL-8*, 5'-AAGGAAAACCTGGGTGCAGAG-3' (forward) and 5'-ATTGCATCTGGCAACCCCTAC-3' (reverse), mouse *Gro-α*, 5'-GCTGGGATTCACC TCAAGAA-3' (forward) and 5'-AGTGGCCATCAGAGCAGTCT-3' (reverse), bacterial *baij* 5'-TCAGGACCTGGAGGCGATCCA-3' (forward) and 5'-TACRTGATCTGGTAGTCCA-3' (reverse), *Clostridium* cluster XI 16S rRNA gene 5'-TGACGGTACYNRKGGAGGAAGCC-3' (forward) and 5'-ACTACGGTTRAGCCGTAGCCTTT-3' (reverse).

In vivo RNAi experiment. 250 μl of siRNA solution (3 mg ml⁻¹) against HSP47 or control siRNA were mixed with 250 μl of complexation buffer and 500 μl of Invivofectamine (Life Technologies), incubated for 30 min at 50 °C, and dialysed at room temperature for 2 h in 1 l of PBS (pH 7.4). Dialysed siRNA-Invivofectamine complex was collected and 3 μg per g (weight) was injected through mice's tail vein twice a week for 15 weeks until killed. The sequences of HSP47 targeting oligo are as follows. 5'-GCACUGCUUGUGAACGCCAU GUUCU-3' (sense), 5'-AGAACAUGGCGUUCACAAGCAGUGC-3' (antisense). As a negative control, Ambion *In vivo* Negative Control #1 siRNA(4457289) was used.

Treatment with DCA, UDCA and DFAIII. Deoxycholic acid (DCA) was dissolved in absolute ethanol and diluted in 66% propylene glycol to reduce the concentration of alcohol to 5%. HFD-fed mice treated with DMBA at neonatal stage were fed a combination of four antibiotics (4Abx) with 40 μg per g (weight) of DCA or vehicle (control) three times per week using a plastic feeding tube at the age of 13 weeks old until killed. Ursodeoxycholic acid (UDCA) tablets (Tanabe-Mitsubishi Pharma) were powdered and dissolved in 66% propylene glycol. HFD-fed mice treated with DMBA at neonatal stage were fed 60 μg per g (weight) of UDCA or vehicle (control) using a plastic feeding tube every day at the age of 15 weeks old until killed. Diffructose anhydride III (DFAIII) was dissolved in saline. HFD-fed mice treated with DMBA at neonatal stage were fed 0.1 mg per g (weight) of DFAIII or vehicle (control) using a plastic feeding tube every day at the age of 17 weeks old until killed.

Bacterial 16S rRNA amplicon sequencing and analysis. Bacterial genomic DNA was isolated from faeces using a QIAamp DNA Stool mini kit (QIAGEN), and 100 ng of DNA was used for PCR for V1–V4 hyper variable regions of the 16S rRNA gene. Twenty five cycles of amplification was performed with universal 16S rRNA primers 27F 5'-AGAGTTTGATCCTGGCTCAG-3' and 519R 5'-GWATTACCGCGGCKGCTG-3' with 10-bp barcode tags using KOD Fx plus DNA polymerase (TOYOBO). All amplicons were sequenced on a 454 Genome Sequencer FLX Titanium platform (Roche Diagnostics and Beckman Coulter Genomics). Quality filter-passed sequence reads were obtained by removing reads that had no both primer sequences, had less than 500 bp in length, had the average quality value (QV) < 25, or were possible chimaeric. Of the filter-passed reads, more than 2,500 sequence reads trimming off both primer sequences for each sample were used and subjected to OTU analysis with the cutoff similarity of 97% identity using QIIME software. Representative sequences from each OTU were blasted to the database in Ribosomal Database Project (RDP) and aligned. The obtained OTU sequences were grouped at class level^{34,35} and were subjected to phylogenetic analysis using MEGA software as described previously³⁵.

Determination of the copy number of faecal bacteria. The copy number of faecal bacteria was calculated from the standard curve of known bacterial copy number by quantitative real-time PCR of 16S rRNA gene using 341f, 5'-CCTACGGGAGGC AGCAG-3' and 534r 5'-ATTACCGCGGCTGCTGG-3' primers as described previously³⁶.

Measurement of serum ALT and AST. The levels of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured using kits from WAKO Pure Chemical Industries, Ltd.

Measurement of serum deoxycholic acid. The metabolomic analysis of mice serum were performed by liquid chromatograph mass spectrometry (LC-MS) in Human Metabolome Technologies Inc. Japan as previously described³⁷. The amount of serum DCA was measured by gas chromatograph mass spectrometry (GC-MS) in the Bile Acid Institute of Junshin Clinic, Japan as described³⁸.

Human subjects. Informed consent was obtained from all patients according to the protocol approved by the ethics committee of the Japanese Foundation for Cancer Research (JFCR).

Statistical analysis. Data were analysed by unpaired *t*-test with Welch correction (two-side) or Mann-Whitney test (two-side). *P*-values less than 0.05 were considered significant.

Cell culture. Murine primary HSCs were isolated as previously described^{18,39}, and were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum in 3% O₂ and 5% CO₂ condition. Human primary HSCs were purchased from Health Science Research Resources Bank and were grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum in 3% O₂ and 5% CO₂ condition.

H-ras sequencing. Total RNA was prepared from HCCs and HSCs isolated from tumour regions using TRIzol reagent (Invitrogen). RNA was converted to cDNA by using oligo (dT) primer and a 330-bp PCR fragment containing exon 2 of *H-ras* gene was amplified with 5'-TGGGGCAGGAGCTCCTGGAT-3' and 5'-GAA GGACTTGGTGTGTTGA-3' primers. PCR fragments were sub-cloned using Target Clone Plus system (TOYOBO) and were sequenced by using Dye-Terminator and Big-Dye cycle sequencing system (Applied Biosystems) as described previously³³.

Abstract

Background: The *EML4-ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion oncogene represents a novel molecular target in a small subset of non-small-cell lung cancers (NSCLCs). The *EML4-ALK* fusion gene occurs generally in NSCLC without mutations in epidermal growth factor receptor (*EGFR*) and *KRAS*.

Case presentation: We report that a case of *EML4-ALK*-positive NSCLC with *EGFR* mutation had a response of stable disease to both an EGFR tyrosine kinase inhibitor (EGFR-TKI) and ALK inhibitor.

Conclusions: We described the first clinical report of a patient with *EML4-ALK*-positive NSCLC with *EGFR* mutation that had a response of stable disease to both single-agent EGFR-TKI and ALK inhibitor. *EML4-ALK* translocation may be associated with resistance to EGFR-TKI, and EGFR signaling may contribute to resistance to ALK inhibitor in *EML4-ALK*-positive NSCLC.

Keywords: *EML4-ALK*, *EGFR* mutation, Lung cancer

Background

The *EML4-ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion oncogene was recently identified as a novel genetic alteration in non-small-cell lung cancer (NSCLC) [1]. *EML4-ALK* fusions have been detected in 2 to 7% of NSCLC patients. Patients harboring *ALK* rearrangements tend to be never and light smokers, have a history of adenocarcinoma, and be younger in age [1-6]. In general, the *EML4-ALK* fusion oncogene existed exclusively in NSCLC patients without the epidermal growth factor receptor (*EGFR*) gene mutation [1,7,8].

ALK inhibitors such as crizotinib are clinically effective in NSCLC patients harboring *ALK* rearrangements [9]. Crizotinib produced a high response rate and prolonged

median progression-free survival among patients with *ALK*-positive NSCLC [9]. Crizotinib was recently approved by the US Food and Drug Administration and Japanese Ministry of Health, Labour and Welfare for the treatment of patients with advanced, *ALK*-rearranged NSCLC.

In this paper, we report a patient with NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation that had a response of stable disease to both an EGFR tyrosine kinase inhibitor (EGFR-TKI) and ALK inhibitor.

Case presentation

In December 2009, a 55-year-old female who had never smoked was noted to have left lung opacity on a routine chest X-ray. No significant previous medical history was reported. Computed tomography (CT) scan of the chest revealed a 1.5 × 1.5 cm nodular lesion in the left upper lobe and hilar lymph node metastasis. Transthoracic needle biopsy histology revealed adenocarcinoma, and the histopathological subtype of the specimen was

Full list of author information is available at the end of the article

papillary adenocarcinoma with signet-ring cell components (Figure 1A-1C). The specimen was positive for periodic acid-Schiff (PAS) (Figure 1C). On immunohistochemical staining, the tumor cells were positive for thyroid transcription factor-1 (TTF-1) (Figure 1D). Laboratory findings were within normal range, except for the carcinoembryonic antigen (CEA) level of 158.0 ng/mL (normal range, 0 to 4.3 ng/mL) in the serum. She had multiple dorsal vertebra metastases (cT1N1M1b, stage IV).

Analysis for *EGFR* gene mutation was performed using a cytological specimen by means of the peptide nucleic acid-locked nucleic acid (PNA-LNA) polymerase-chain-reaction (PCR) clamp method as described previously [10,11]. The specimen showed a deletion in exon 19 (L747-A750del T751S). We collected mRNA from the same tumor specimens using Pinpoint Slide RNA Isolation System in order to clarify whether there was *EML4-ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion gene in each tumor. Reverse transcription polymerase-chain-reaction (RT-PCR) followed by direct sequencing confirmed the presence of *EML4-ALK* variant 2 [1] (Figure 2). In addition, *EML4-ALK* was identified by using fluorescent in situ hybridization (FISH) for *ALK* rearrangements (Figure 3B) and was confirmed by immunohistochemistry for *ALK* expression in tumor [2] (Figure 3A).

A platinum doublet was chosen as first line therapy according to existing treatment protocol in 2009. Four

cycles of combination chemotherapy comprising cisplatin and pemetrexed was administered at 3-week intervals. She was judged as having a stable disease. After 7 months, spinal magnetic resonance imaging (MRI) revealed progression of the dorsal vertebra lesions. Therefore, EGFR-TKI was chosen as a 2nd-line therapy. She received gefitinib therapy at 250 mg/day administered orally for 2 months. CT imaging of the chest showed that the pulmonary nodule was not growing after gefitinib therapy, and the tumor marker levels had not changed. However, spinal MRI demonstrated growing dorsal vertebra metastases 2 months after the start of gefitinib therapy. The carcinoembryonic antigen (CEA) level increased from 117 ng/ml to 250 ng/ml. Therefore, the patient was judged as having progressive disease. After local radiation therapy with a total of 30 Gy for dorsal metastases, a second EGFR-TKI was chosen given the stable primary disease. She received another EGFR-TKI, erlotinib (150 mg/day), as 3rd-line therapy. After being progression-free for 3 months, spinal MRI revealed a growing thoracic vertebra metastasis. She received 4th-line treatment with 2 cycles of docetaxel (DTX). However, her disease progressed 6 months later. Finally, she received a targeted inhibitor of *ALK*. The patient initially had SD associated with a temporary decrease in the CEA level from 743 ng/ml to 520 ng/ml, but her disease progressed after 4 months of therapy. The *ALK* inhibitor treatment was

Figure 1 Histology of the primary tumour. (A) and (B) shows a papillary adenocarcinoma (hematoxylin and eosin 200× magnification), (C) a mucin stain shows positive for both signet-ring and papillary morphology (PAS, 400× magnification). (D) immunohistochemical analysis of lung adenocarcinoma specimens with *EML4-ALK* fusion using a monoclonal anti-TTF-1 antibody (200× magnification).

ceased and full supportive care was given. All lines of therapy were well tolerated.

Discussion

We presented a patient with NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation that had a response of stable disease to both *EGFR*-TKI and *ALK* inhibitors. The presence of *EML4-ALK* generally seems to be mutually exclusive of the presence of *EGFR* or *KRAS* mutations in NSCLC [1,7,8]. Previous reports showed twelve cases of *EML4-ALK*-positive lung cancer with *EGFR* mutation [3,12-17]. Only one patient with harboring *ALK* translocation and *EGFR* mutation was treated by *ALK* inhibitor has been reported [17]. Lee et al.

reported two *ALK*-positive and *EGFR*-mutant NSCLC patient who did not respond to *EGFR*-TKI but achieved a durable partial response to *ALK* inhibitor [17]. The present patient was a woman with no history of smoking. Her pathological diagnosis was papillary adenocarcinoma with a signet-ring cell component, which was consistent with the previously reported characteristics of *EML4-ALK*-positive lung adenocarcinoma except for the *EGFR* mutation status [1-6]. It was reported that *EGFR*-TKI therapy among patients with advanced NSCLC and *EGFR* mutations revealed a response rate of more than 60% and progression-free survival of 9 to 14 months [11,18,19]. In addition, recent reports showed that *ALK* inhibition in NSCLC patients with the *ALK* rearrangement resulted in tumor shrinkage or stable disease in most patients [9]. Unfortunately, *EGFR*-TKI treatment was not effective in the tumor regression nor tumor marker level of present patient (disease might be controlled), but treatment with an *ALK* inhibitor resulted in SD with decreasing tumor markers. Therefore, this case showed that *ALK* rearrangement might be superior to *EGFR* mutation for the driver mutation.

It was reported that *EML4-ALK* fusion was associated with resistance to *EGFR*-TKIs [20]. Patients with NSCLC in the *EML4-ALK* cohort and the wild type cohort showed similar response rates to platinum-based combination chemotherapy and no difference in overall survival [20]. Whereas *EGFR* mutations confer sensitivity to *EGFR*-TKIs, *EML4-ALK* is strongly associated with resistance to *EGFR*-TKIs. In a previous case of concomitant *EGFR* mutation and *ALK* translocation, the patient presented the most durable response to an *EGFR*-TKI and was a case demonstrating no *EML4-ALK* expression by immunohistochemistry with an *EML4-ALK* rearrangement characterized by an isolated 3_ FISH signal [12]. Our patient presented a concurrent *EML4-ALK* rearrangement and *ALK* expression by immunohistochemistry; however, *EGFR*-TKI was not effective.

Among patients with both *EML4-ALK* rearrangement and *EGFR* mutation, *in vitro* studies showed that *EGFR* signaling can contribute to *ALK* inhibitor resistance in *EML4-ALK* NSCLC [14]. In addition, these findings suggested that a cancer cell line that harbors a concurrent

Figure 3 Diagnosis of an *EML4-ALK*-positive non-small cell lung cancer. (A) Immunostaining for *ALK* protein expression in tumor cells. (B) The results of a break-apart FISH assay of tumor cells from a patient with rearrangement of the gene encoding *ALK*.

ALK rearrangement and an *EGFR* mutation would be expected to be resistant to both single agent *ALK* and *EGFR* inhibitors [14]. We suggest that the combination of both *ALK* and *EGFR* inhibitors as early-line treatment may represent an effective therapy for this subset of NSCLC patients.

Conclusions

This is the first clinical report of a patient with *EML4-ALK*-positive NSCLC with *EGFR* mutation that had a response of stable disease to both single-agent *EGFR*-TKI and *ALK* inhibitor. The *EML4-ALK* fusion gene defines a new molecular subset of NSCLCs with distinct clinical and pathologic features. NSCLCs with *ALK* rearrangement are highly sensitive to *ALK* inhibition. However, *EGFR* signaling may contribute to *ALK* inhibitor resistance in *EML4-ALK* NSCLC. Therefore, we suggest that this provides a translational opportunity whereby laboratory studies should be undertaken to understand the biological link between *ALK* rearrangement and *EGFR* mutation, with a view to establishing whether there is preclinical justification for using combination therapy for NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation.

Consent

Written informed consent was obtained from the patient for publication of this case report and accompanying images.

Activity of EGFR-tyrosine kinase and ALK inhibitors for *EML4-ALK*-rearranged non-small-cell lung cancer harbored coexisting *EGFR* mutation

Akihiko Miyanaga¹, Kumi Shimizu¹, Rintaro Noro¹, Masahiro Seike¹, Kazuhiro Kitamura¹, Seiji Kosaihiro¹, Yuji Minegishi¹, Takehito Shukuya⁷, Akinobu Yoshimura^{1,8}, Masashi Kawamoto^{2,3}, Shinichi Tsuchiya², Koichi Hagiwara⁴, Manabu Soda⁵, Kengo Takeuchi⁶, Nobuyuki Yamamoto⁷, Hiroyuki Mano⁵, Yuichi Ishikawa⁶ and Akihiko Gemma^{1*}

Abstract

Background: The *EML4-ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion oncogene represents a novel molecular target in a small subset of non-small-cell lung cancers (NSCLCs). The *EML4-ALK* fusion gene occurs generally in NSCLC without mutations in epidermal growth factor receptor (*EGFR*) and *KRAS*.

Case presentation: We report that a case of *EML4-ALK*-positive NSCLC with *EGFR* mutation had a response of stable disease to both an EGFR tyrosine kinase inhibitor (EGFR-TKI) and ALK inhibitor.

Conclusions: We described the first clinical report of a patient with *EML4-ALK*-positive NSCLC with *EGFR* mutation that had a response of stable disease to both single-agent EGFR-TKI and ALK inhibitor. *EML4-ALK* translocation may be associated with resistance to EGFR-TKI, and EGFR signaling may contribute to resistance to ALK inhibitor in *EML4-ALK*-positive NSCLC.

Keywords: *EML4-ALK*, *EGFR* mutation, Lung cancer

Background

The *EML4-ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion oncogene was recently identified as a novel genetic alteration in non-small-cell lung cancer (NSCLC) [1]. *EML4-ALK* fusions have been detected in 2 to 7% of NSCLC patients. Patients harboring *ALK* rearrangements tend to be never and light smokers, have a history of adenocarcinoma, and be younger in age [1-6]. In general, the *EML4-ALK* fusion oncogene existed exclusively in NSCLC patients without the epidermal growth factor receptor (*EGFR*) gene mutation [1,7,8].

ALK inhibitors such as crizotinib are clinically effective in NSCLC patients harboring *ALK* rearrangements [9]. Crizotinib produced a high response rate and prolonged

median progression-free survival among patients with *ALK*-positive NSCLC [9]. Crizotinib was recently approved by the US Food and Drug Administration and Japanese Ministry of Health, Labour and Welfare for the treatment of patients with advanced, *ALK*-rearranged NSCLC.

In this paper, we report a patient with NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation that had a response of stable disease to both an EGFR tyrosine kinase inhibitor (EGFR-TKI) and ALK inhibitor.

Case presentation

In December 2009, a 55-year-old female who had never smoked was noted to have left lung opacity on a routine chest X-ray. No significant previous medical history was reported. Computed tomography (CT) scan of the chest revealed a 1.5 × 1.5 cm nodular lesion in the left upper lobe and hilar lymph node metastasis. Transthoracic needle biopsy histology revealed adenocarcinoma, and the histopathological subtype of the specimen was

* Correspondence: agemma@nms.ac.jp

Full list of author information is available at the end of the article

papillary adenocarcinoma with signet-ring cell components (Figure 1A-1C). The specimen was positive for periodic acid–Schiff (PAS) (Figure 1C). On immunohistochemical staining, the tumor cells were positive for thyroid transcription factor-1 (TTF-1) (Figure 1D). Laboratory findings were within normal range, except for the carcinoembryonic antigen (CEA) level of 158.0 ng/mL (normal range, 0 to 4.3 ng/mL) in the serum. She had multiple dorsal vertebra metastases (cT1N1M1b, stage IV).

Analysis for *EGFR* gene mutation was performed using a cytological specimen by means of the peptide nucleic acid–locked nucleic acid (PNA–LNA) polymerase-chain-reaction (PCR) clamp method as described previously [10,11]. The specimen showed a deletion in exon 19 (L747–A750del T751S). We collected mRNA from the same tumor specimens using Pinpoint Slide RNA Isolation System in order to clarify whether there was *EML4–ALK* (echinoderm microtubule-associated protein-like 4 gene and the anaplastic lymphoma kinase gene) fusion gene in each tumor. Reverse transcription polymerase-chain-reaction (RT-PCR) followed by direct sequencing confirmed the presence of *EML4–ALK* variant 2 [1] (Figure 2). In addition, *EML4–ALK* was identified by using fluorescent in situ hybridization (FISH) for *ALK* rearrangements (Figure 3B) and was confirmed by immunohistochemistry for *ALK* expression in tumor [2] (Figure 3A).

A platinum doublet was chosen as first line therapy according to existing treatment protocol in 2009. Four

cycles of combination chemotherapy comprising cisplatin and pemetrexed was administered at 3-week intervals. She was judged as having a stable disease. After 7 months, spinal magnetic resonance imaging (MRI) revealed progression of the dorsal vertebra lesions. Therefore, EGFR-TKI was chosen as a 2nd-line therapy. She received gefitinib therapy at 250 mg/day administered orally for 2 months. CT imaging of the chest showed that the pulmonary nodule was not growing after gefitinib therapy, and the tumor marker levels had not changed. However, spinal MRI demonstrated growing dorsal vertebra metastases 2 months after the start of gefitinib therapy. The carcinoembryonic antigen (CEA) level increased from 117 ng/ml to 250 ng/ml. Therefore, the patient was judged as having progressive disease. After local radiation therapy with a total of 30 Gy for dorsal metastases, a second EGFR-TKI was chosen given the stable primary disease. She received another EGFR-TKI, erlotinib (150 mg/day), as 3rd-line therapy. After being progression-free for 3 months, spinal MRI revealed a growing thoracic vertebra metastasis. She received 4th-line treatment with 2 cycles of docetaxel (DTX). However, her disease progressed 6 months later. Finally, she received a targeted inhibitor of *ALK*. The patient initially had SD associated with a temporary decrease in the CEA level from 743 ng/ml to 520 ng/ml, but her disease progressed after 4 months of therapy. The *ALK* inhibitor treatment was

ceased and full supportive care was given. All lines of therapy were well tolerated.

Discussion

We presented a patient with NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation that had a response of stable disease to both *EGFR*-TKI and *ALK* inhibitors. The presence of *EML4-ALK* generally seems to be mutually exclusive of the presence of *EGFR* or *KRAS* mutations in NSCLC [1,7,8]. Previous reports showed twelve cases of *EML4-ALK*-positive lung cancer with *EGFR* mutation [3,12-17]. Only one patient with harboring *ALK* translocation and *EGFR* mutation was treated by *ALK* inhibitor has been reported [17]. Lee et al.

reported two *ALK*-positive and *EGFR*-mutant NSCLC patient who did not respond to *EGFR*-TKI but achieved a durable partial response to *ALK* inhibitor [17]. The present patient was a woman with no history of smoking. Her pathological diagnosis was papillary adenocarcinoma with a signet-ring cell component, which was consistent with the previously reported characteristics of *EML4-ALK*-positive lung adenocarcinoma except for the *EGFR* mutation status [1-6]. It was reported that *EGFR*-TKI therapy among patients with advanced NSCLC and *EGFR* mutations revealed a response rate of more than 60% and progression-free survival of 9 to 14 months [11,18,19]. In addition, recent reports showed that *ALK* inhibition in NSCLC patients with the *ALK* rearrangement resulted in tumor shrinkage or stable disease in most patients [9]. Unfortunately, *EGFR*-TKI treatment was not effective in the tumor regression nor tumor marker level of present patient (disease might be controlled), but treatment with an *ALK* inhibitor resulted in SD with decreasing tumor markers. Therefore, this case showed that *ALK* rearrangement might be superior to *EGFR* mutation for the driver mutation.

It was reported that *EML4-ALK* fusion was associated with resistance to *EGFR*-TKIs [20]. Patients with NSCLC in the *EML4-ALK* cohort and the wild type cohort showed similar response rates to platinum-based combination chemotherapy and no difference in overall survival [20]. Whereas *EGFR* mutations confer sensitivity to *EGFR*-TKIs, *EML4-ALK* is strongly associated with resistance to *EGFR*-TKIs. In a previous case of concomitant *EGFR* mutation and *ALK* translocation, the patient presented the most durable response to an *EGFR*-TKI and was a case demonstrating no *EML4-ALK* expression by immunohistochemistry with an *EML4-ALK* rearrangement characterized by an isolated 3_ FISH signal [12]. Our patient presented a concurrent *EML4-ALK* rearrangement and *ALK* expression by immunohistochemistry; however, *EGFR*-TKI was not effective.

Among patients with both *EML4-ALK* rearrangement and *EGFR* mutation, *in vitro* studies showed that *EGFR* signaling can contribute to *ALK* inhibitor resistance in *EML4-ALK* NSCLC [14]. In addition, these findings suggested that a cancer cell line that harbors a concurrent

Figure 3 Diagnosis of an *EML4-ALK*-positive non-small cell lung cancer. (A) Immunostaining for *ALK* protein expression in tumor cells. (B) The results of a break-apart FISH assay of tumor cells from a patient with rearrangement of the gene encoding *ALK*.

ALK rearrangement and an *EGFR* mutation would be expected to be resistant to both single agent *ALK* and *EGFR* inhibitors [14]. We suggest that the combination of both *ALK* and *EGFR* inhibitors as early-line treatment may represent an effective therapy for this subset of NSCLC patients.

Conclusions

This is the first clinical report of a patient with *EML4-ALK*-positive NSCLC with *EGFR* mutation that had a response of stable disease to both single-agent *EGFR*-TKI and *ALK* inhibitor. The *EML4-ALK* fusion gene defines a new molecular subset of NSCLCs with distinct clinical and pathologic features. NSCLCs with *ALK* rearrangement are highly sensitive to *ALK* inhibition. However, *EGFR* signaling may contribute to *ALK* inhibitor resistance in *EML4-ALK* NSCLC. Therefore, we suggest that this provides a translational opportunity whereby laboratory studies should be undertaken to understand the biological link between *ALK* rearrangement and *EGFR* mutation, with a view to establishing whether there is preclinical justification for using combination therapy for NSCLC with concomitant *ALK* rearrangement and *EGFR* mutation.

Consent

Written informed consent was obtained from the patient for publication of this case report and accompanying images.

Summary Patients with small cell lung carcinoma (SCLC) rarely demonstrate long-term survival. We previously reported that gene expression profiling identified a subset of SCLC with good prognosis in surgical cases. To find an easier way to routinely identify SCLC belonging to this subset, we conducted the present study with a hypothesis that neuroendocrine (NE) or basaloid (BA) phenotypes may influence prognosis. To confirm the subset, we used an array platform to analyze fresh samples. Because inoperable cases may differ from surgical cases, we enrolled 51 biopsy cases and 43 resected samples. To evaluate NE and BA phenotypes, we used NE (synaptophysin, chromogranin A, and CD56) and BA (p63 and CK34βE12) markers. To varying extents, expression profiling based on the array platform

duplicated the subsets. For NE phenotypes, 77% of surgical cases and 100% of biopsy cases were positive for at least 1 marker. For BA phenotypes, only 19% of surgical cases were positive for at least 1 marker, whereas there were no positive biopsy cases. Cases undergoing surgery were categorized based on NE and BA immunoreactivity; 58% into NE+BA⁻, 19% into NE+BA⁺, 23% into NE-BA⁻, and 0 into NE-BA⁺ groups. NE⁻ patients (n = 10) demonstrated a significantly better prognosis ($P = .0306$) than their NE⁺ counterparts (n = 33), whereas no survival difference was evident between the BA⁺ and BA⁻ groups. Multivariate analyses showed that NE positivity was an independent prognostic factor. In conclusion, the SCLC subset with good prognosis is identified by low NE marker expression, which was found only in surgical cases.

1. Introduction

Small cell lung carcinoma (SCLC) accounts for about 15% of all lung cancers, and its high proliferative activity generally leads to early metastasis to lymph nodes and distant organs. It is known that, although more sensitive to chemotherapy and irradiation than non-SCLCs [1,5], SCLCs tend to recur in about 70% of cases [6]. Some cases that are initially misdiagnosed are only found to be SCLC after resection [7]. Including these cases, it has been found that stage I SCLC has only a 42% to 66% 5-year survival, which is much lower than for non-SCLCs [8,9]. These statistics reflect a disparate course, with some patients with SCLC surviving for a long time after therapy, whereas others appear insensitive to chemotherapy and irradiation, implying considerable heterogeneity.

SCLC has distinct histologic characteristics such as scant cytoplasm (high nucleocytoplasmic [N/C] ratio), ill-defined cell borders, finely granular nuclear chromatin, absent or inconspicuous nucleoli, round to spindle shaped, nuclear molding and rosette formation, extensive necrosis, and a high mitotic rate [10]. Surgically resected tumors show somewhat different histology such as larger cell sizes, occasional conspicuous nucleoli, and vesicular nuclear chromatin [7]. It is necessary to prove neuroendocrine (NE) differentiation by immunohistochemistry (IHC) or electron microscopy for the diagnosis of large cell NE carcinoma (LCNEC). However, according to the World Health Organization (WHO) classification [10], this is not mandatory for SCLC. Nevertheless, without IHC, it is sometimes difficult to differentiate an SCLC from a poorly differentiated non-SCLC composed of small-sized cells with a high N/C ratio, such as basaloid (BA) carcinoma. In such cases, immunohistochemical markers for BA cells are useful in distinguishing NE carcinomas from poorly differentiated squamous cell carcinomas and BA carcinomas [11,12]. It is important to distinguish such carcinomas from SCLC because they may have a better prognosis than SCLC, although BA carcinoma has a poorer prognosis than usual squamous cell carcinomas.

We previously identified a subset of SCLC with good prognosis by global gene expression profiling using custom-made complementary DNA (cDNA) microarrays [13],

showing that differentially expressed genes included NE-related genes, implying that long-term survival is not simply a matter of chance. To further characterize this subset and define a more readily accessible technique, such as IHC, to identify this subset, we set out this study by hypothesizing that a degree of NE differentiation or a basal cell nature may be related to prognosis. Because this subset had been delineated in surgically resected cases and inoperable cases may possibly differ from surgical cases, we also enrolled inoperable cases using available biopsy materials. First, we confirmed the existence of the subset using another platform of gene expression profiling and then performed IHC with NE and basal cell markers for surgical and biopsied cases. We paid particular attention to excluding atypical carcinoids.

2. Materials and methods

2.1. Patients and tumor samples

Surgical samples of SCLC are scarce: during the period from January 1990 to December 2004, a total of 1568 lung cancers were resected surgically at the Cancer Institute Hospital, Japanese Foundation for Cancer Research, Tokyo, Japan. Among these cancers, only 56 cases (3.6%) were found to be SCLC by pathological examination of resected materials. In this study, we enrolled a total of 96 SCLC cases, which were composed of 45 surgical cases and 51 inoperable cases with only biopsy specimens available. Histologic diagnosis of SCLC was made according to the 2004 WHO classification [10], relying only on hematoxylin and eosin (H&E) staining. Cases with atypical histology were examined by a panel of Japanese expert pathologists organized by an NE tumor study group [9], supported by the Ministry of Health, Labour and Welfare. Also, a few of the atypical cases were presented at the Pathology Committee meeting of the International Association for the Study of Lung Cancer, held in Tokyo, Japan. Atypical carcinoids were carefully excluded, with special attention to mitosis and cell morphology. Excluding some SCLC cases with extensive degeneration due to induction therapy, or with insufficient tumor cells remaining after chemotherapy, 45 surgical tumors were used for this
