RESULTS

Profiles of EBV-HLH Patients

Clinical and laboratory findings of 22 patients at diagnosis are shown in Table I. The male/female ratio was 0.69. HLH occurred at median 5.5 years of age ranging from 11 months to 41 years. During the follow-up period (median: 2 years, range: 5 months–10 years), no survivors recurred HLH or developed immunodeficiency or lymphoma. T-cell infection was determined in 15 of 16 (94%) patients studied, 12 and 7 of whom showed EBV and TCR clonality, respectively (Fig. 1). Of 15 T-cell infections, $CD8^+$ subset was targeted in 9 patients examined. One B-cell infection was found in the series. Nineteen and three patients were determined as having primary infection and reactivation at the time of diagnosis, respectively. When the age of 16 patients (<15 years of age) was plotted according to the year, all but one had primary infection (Fig. 2). The primary infection occurred at higher age 2006–2010 than 1999–2005 ($P = 0.031$).

Treatment Outcomes of EBV-HLH Patients

Cohort diagram for the treatment outcome of 22 patients are shown in Figure 3. Two patients remitted spontaneously. A 14-month-old male (index case-1) showed high fever for 9 days and hepatosplenomegaly. Laboratory data showed WBC 2.19×10^9/L, hemoglobin 9.9 g/dl, platelet 48×10^9/L, CRP 0.23 mg/dl, LDH 517 U/L, and ferritin 738 ng/ml. EBV load (2.0×10^4 copies/ml) and negative EBNA indicated primary infection. At the day of admission, he had defervescence. A 21-month-old female (index-2) showed fever for 8 days and hepatosplenomegaly. Laboratory data showed WBC 2.52×10^9/L, hemoglobin 10.5 g/dl, platelet 25×10^9/L, LDH 3293 U/L, sIL-2R 4923 U/ml, and ferritin 8851 ng/ml. EBV load (1.0×10^5 copies/ml) and negative EBNA indicated primary infection. At the next day of admission, she had defervescence. A 10-year-old female was a representative ITx case showing high fever for 5 days and hepatosplenomegaly. Complete blood counts showed WBC 40.7×10^9/L, hemoglobin was 13.0 g/dl and platelet 68×10^9/L. PB smear revealed neutrophils 9.0%, lymphocytes 8.5%, atypical lymphocytes 1.5%, large granular lymphocytes 20% and unclassified cells 58.5%, mostly expressing CD3, CD8, and HLA-DR assessed by flow-cytometry. Laboratory data showed LDH 2,122 U/L, sIL-2R 8,684 ng/ml, and ferritin 5,436 ng/ml. EBV load (2.0×10^5 copies/ml), positive VCA-IgG and -IgM and negative EBNA indicated primary infection. On the next day after the start of γ-globulin (1 g/kg) and PSL (1.5 mg/kg/day), she had defervescence. Southern blotting revealed clonally proliferating EBV-positive $CD8^+$T-cells.

Of 20 patients with ITx, 16, 16, and 13 received γ-globulin, PSL, including 5 high dose methyl-PSL, and CSA, respectively. No HLH recurred in 11 patients who received CSA for 6 months after the remission. CTx was added to 8 patients; one, the other one and 3 patient(s) attained the remission after VP16 only, VP16 + CY, and CHOP-VP16, respectively. Of eight patients with CTx, a 41-year-old male died of HLH, and a 15-year-old male died after subsequent SCT. A 6-year-old female underwent successful allogeneic UCBT as reported elsewhere [27]. The remaining five patients attained remission with 100% Karnofsky score. As shown in Figure 4, 12 of 16 children <15 years of age (75%) required no CTx for the control of HLH, while 2 of 6 patients >16 years of age (33%) obtained remission without CTx.

Comparative Study on the Requirement of VP16-Based Chemotherapy

Clinical variables at diagnosis were studied in patients who underwent CTx or not (Table I). Febrile days until the treatment ($P = 0.011$), LDH ($P = 0.028$) and sIL-2R levels ($P = 0.018$) at the time of diagnosis were higher in CTx-group than seen in non-CTx group. The observation period was marginally longer in CTx- than non-CTx group ($P = 0.042$). To search the predictors requiring CTx, multiple logistic regression analysis was performed (Table II). As all three EBV-reactivated patients underwent CTx, EBNA was excluded for the analysis. When 22 patients were analyzed for 12 variables excluding sIL-2R, longer febrile days until the first ITx (odds ratio 1.10, $P = 0.017$) was associated with CTx. When 12 patients were analyzed for 13 variables

TABLE I. Comparison of Variables Between Etoposide-Required Patients and Non-Required Patients

	Total	Cytotoxic	Non-cytotoxic	*P*-value
Number of patients	22	8	14

EBV, Epstein–Barr virus; ALT, alanine aminotransferase; LDH, lactate dehydrogenase; IL-2, interleukin-2; yrs, years. All variables were expressed as median (range). Each *P*-value was calculated by Fisher's exact test*, Wilcoxon-test**, $\log_{10}$ *t*-test*** and *t*-test****.

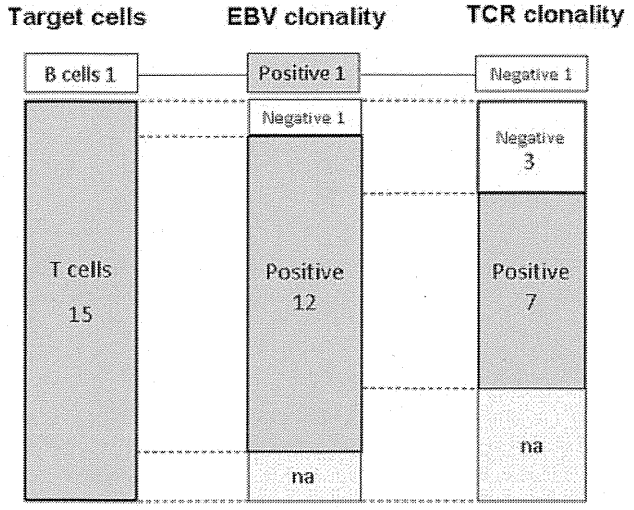

Fig. 1. Target cells of infection and clonal analyses in 16 patients with Epstein–Barr virus associated hemophagocytic lymphohistiocytosis (EBV-HLH). Major targeted cells were assessed by the copy number of EBV DNA in sorted cells. Clonal analyses were assessed by Southern blotting probed with EBV-terminal repeat sequences and T-cell receptor (TCR) genes. na: Not assessed.

including sIL-2R, sIL-2R levels (odds ratio 1.39, $P = 0.017$) was only selected in association with CTx.

DISCUSSION

We notably observed that EBV-HLH mostly occurred at primary infection, 64% of which remitted without VP16 therapy including spontaneous resolution. The target of infection was clonally proliferating $CD8^+$T-cells. Patients >15 years of age having positive EBNA at diagnosis had intractable course. Prolonged fever or high sIL-2R levels were indicated as the independent risk factors for requiring CTx. The early ITx could more effectively treat EBV-HLH than expected, although universal

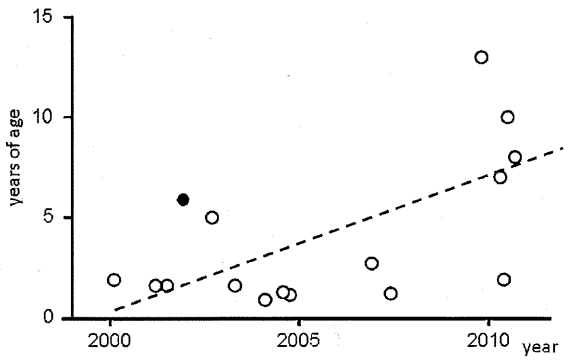

Fig. 2. Age and calendar year at the time of diagnosis in 16 patients <15 years of age. Open circle (○) means primary infection, and closed circle (•) represents reactivation of EBV. EBV status was serologically assessed by the positivity of EBNA at the time of diagnosis. Dashed line is the linear slope with correlation coefficient of 0.403; $P = 0.0101$.

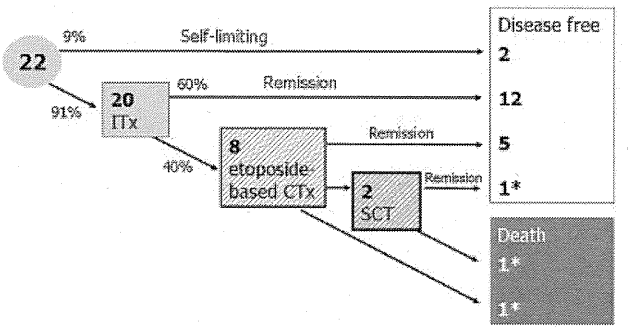

Fig. 3. Cohort diagram for the treatment course of 22 EBV-HLH patients. ITx: immunosuppresive/modulation therapy consisting of prednisolone, cyclosporine-A, and high dose therapy of γ-globulin. CTx: etoposide-based cytotoxic therapy including multidrug chemotherapy. SCT: allogeneic hematopoietic stem cell transplantation.

applicability of our strategy needs to be assessed. The treatment response suggested the modulating T-cell activation, as well as a progressive nature of EBV-driven T-lymphoproliferation.

The primary issue is the entity of EBV-HLH. In this study, EBV-HLH is defined as a non-inherited HLH having high EBV load but no evidence of malignancy or CAEBV [22]. Even using our criteria, acute IM, CAEBV and EBV-positive peripheral T-cell lymphoma might be incorporated into the subjects. Complete exclusion of inherited HLH is difficult. VP16 therapy improved the patient survival of FHL [26] and EBV-HLH [28] until 2000. Imashuku et al. [29] revealed a survival benefit if VP16 therapy was started within 4 weeks of diagnosis, while more than half of cases first underwent VP16 therapy in the multicenter study. HLH94/2004 originally aimed to control FHL patients until SCT. The feasibility of VP16 therapy for EBV-HLH has been an open question because several patients successfully remitted after ITx [7,15,30,31]. As reported here and by Belyea et al. [19], spontaneous remission occurred in patients <20 years of age on primary infection. In our study, one patient who had EBV-loaded B-cells and T-cells on primary infection was successfully treated with ITx, although it was unclear which lymphocytes carried clonal EBV. Both Japanese and non-Japanese studies revealed that T-cells [7–9,15] and rarely NK-cells [16] were the target of infection in EBV-HLH patients. More than 80% of Asian T-cell type CAEBV overlap the entity of "systemic EBV^+T-cell LPD of childhood" by the WHO2008 classification [10]. However, EBV-HLH is hardly defined pathologically. EBV-HLH patients on the virus reactivation might have a poor prognosis [31]. In our study, all three EBV-reactivated patients underwent CTx ± SCT, and two adult patients of them died. High EBV load indicated the poor treatment response [32]. However, irrespective of EBV load, 14 of 19 patients on primary infection (74%) attained resolution without CTx. None of 14 patients had late relapse of HLH. Advanced age at presentation of pediatric EBV-HLH in these 5 years (Fig. 2) reflected the increasing age of primary infection in Japan [33]. The ITx response in adolescent primary infection was favorable. Taken together, the clinical entity of "true EBV-HLH of childhood" could be defined as "systemic EBV-positive $CD8^+$T-cell LPD in immunocompetent subjects on the primary infection" and be treated with ITx during the early phase of disease.

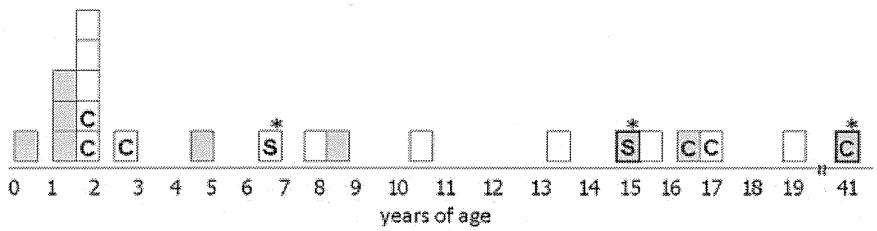

Fig. 4. Sex, age at the time of diagnosis, EBV status, and treatment modality in 22 patients. Asterisk means the reactivation of EBV. Bold square represents death. Closed and open squares mean male and female, respectively. C: etoposide-based chemotherapy, S: chemotherapy and hematopoietic stem cell transplantation.

The prognosis of adult EBV-HLH is poor. Ahn et al. [18] reported that only 2 of 15 adult patients with EBV-HLH survived after ITx in Korea. Elazary et al. [17] reported a fatal case of a 27-year-old Jewish male with EBV-HLH at the primary infection. Sonke et al. [14] reported three fatal cases of adult onset CAEBV and HLH, one of whom showed positive EBV VCA-IgM and negative EBNA and systemic infiltration of EBV^+ polyclonal $CD8^+$T cells. Arai et al. [34] have reported five refractory cases of adult onset CAEBV, one of whom showed EBV^+ monoclonal $CD8^+$T cells and negative EBNA. Further study is needed for the pathogenesis of adult onset EBV-HLH.

Recurrent flare-up of disease activity is a critical issue in the treatment of EBV-HLH. There is no recommended therapy for patients who failed 8 weeks of HLH2004 protocol. EBV-infected T-cells evade the immune surveillance and could proliferate [6,24,35,36]. In our study, 8 of 22 EBV-HLH patients (36%) required CTx because of relapsing or persistent fever within 3 weeks after the initial ITx. Based on the subclinical activation represented by high IL-18 levels [37], CSA therapy was prolonged for refractory cases but failed in eight patients. Multivariate analyses indicated longer fever and higher sIL-2R levels as the risk of requiring CTx. It may raise the potential role of early ITx to avoid falling into the vicious cycle of hypercytokinemia as in the early VP16 therapy [29]. Alternately, high levels of sIL-2R and LDH might imply the nature of LPD. A snapshot of laboratory profiles hardly stratified the treatment arm of EBV-HLH, but our study raised a potential indicator of non-CTx. Clinical rationale of ITx, CTx and SCT for EBV-HLH is distinct from that for primary HLH, Asian type CAEBV (T-cell infection) [38,39], and Caucasian type CAEBV (B-cell infection) [40]. Early ITx, but not to be delayed VP16 therapy, may be recommended for EBV-HLH of childhood that meets all chosen criteria. The cytokine blockades of tumor necrosis factor-α or interferon-γ pathway are promising non-cytotoxic agents for the control of HLH [19]. Our strategy with limited number of cases may not be applicable to all patients beyond the racial backgrounds. Further prospective studies on the cellular tropism and EBV status are needed to confirm the preliminary results and establish the optimal treatment of EBV-HLH.

TABLE II. Variables Associated With the Requirement of Etoposide-Based Chemotherapy

Variables	Odds ratio	95% Confidence interval	*P*-value
Febrile days until the first ITx (1-day gain)[a]	1.10	1.01–1.23	0.017
sIL-2R (1×10^3 IU/L gain)[b]	1.39	1.04–2.52	0.017

ITx: immunotherapy with corticosteroid, cyclosporine-A, and/or γ globulin. sIL-2R: soluble IL-2 receptor. Multiple logistic regression analysis was performed to examine associations between variables at diagnosis and required chemotherapy, simultaneously adjusting for potential confounding factors by covariates. Likelihood ratio tests were used to assess statistical significance. [a]Twenty-two patients analyzed for 12 variables excluding sIL-2R; [b]Twelve patients for 13 variables including sIL-2R.

Letter to the Editor

Common variable immunodeficiency classification by quantifying T-cell receptor and immunoglobulin κ-deleting recombination excision circles

To the Editor:

Common variable immunodeficiency (CVID) is the most frequent primary immunodeficiency associated with hypogammaglobulinemia and other various clinical manifestations. CVID was originally reported to be a disease primarily caused by defective B-cell function, with defective terminal B-cell differentiation rendering B cells unable to produce immunoglobulin. However, combined immunodeficiency (CID) involving both defective B and T cells is often misdiagnosed as CVID.[1] Indeed, one study reported that $CD4^+$ T-cell numbers were decreased in 29% of 473 patients with CVID[2]; similarly, another study found that naive T-cell numbers were markedly reduced in 44% (11/25) of patients with CVID.[3] These observations indicated that a subgroup of patients with clinically diagnosed CVID is T-cell deficient. Consistently, some patients with CVID have complications that might be related to T-cell deficiency, including opportunistic infections, autoimmune diseases, and malignancies, which is similar to that observed in patients with CID.[1,4] Therefore identifying novel markers to better classify CVID and distinguish CID from CVID will be required to best manage medical treatment for CVID.

We recently performed real-time PCR-based quantification of T-cell receptor excision circles (TREC) and signal joint immunoglobulin κ-deleting recombination excision circles (KREC) for mass screening of severe combined immunodeficiency (SCID)[5] and B-lymphocyte deficiency[6] in neonates. TREC and KREC are associated with T-cell and B-cell neogenesis, respectively.[7] Here we retrospectively report that TREC and KREC are useful for classifying patients with clinically diagnosed CVID.

Hypogammaglobulinemic patients (n = 113) were referred to our hospital for immunodeficiency from 2005-2011, and the following patients were excluded from the CVID pool by estimating their SCID genes based on clinical manifestations and lymphocyte subset analysis: 18 patients with SCID diagnoses; 14 patients less than 2 years of age (transient infantile hypogammaglobulinemia); 10 patients with IgM levels of greater than 100 mg/dL (hyper-IgM syndrome); 26 patients with diseases other than CVID caused by known gene alterations (10 with X-linked agammaglobulinemia and 11 with hyper-IgM syndrome [*CD40L* or *AICDA* mutated]), (2 with DiGeorge syndrome, and 3 with *FOXP3*, *IKBKG*, or *6p* deletions); and 5 patients with drug-induced hypogammaglobulinemia. The remaining 40 patients with decreased IgG (≥2 SDs below the mean for age), IgM, and/or IgA levels, as well as absent isohemagglutinins, poor response to vaccines, or both were included in this study as patients with CVID and analyzed for TREC/KREC levels, retrospectively.

Ages of patients with CVID ranged from 2 to 52 years (median age, 15.5 years). The sex ratio of the patients was 21 male/19 female patients. Serum IgG, IgA, and IgM levels were 370 ± 33 mg/dL (0-716 mg/dL), 30 ± 7 mg/dL (1-196 mg/dL), and 40 ± 6 mg/dL (2-213 mg/dL), respectively. TREC and KREC quantification was performed by using DNA samples extracted from peripheral blood, as reported previously.[5,6] Clinical symptoms were then assessed retrospectively. The study protocol was approved by the National Defense Medical College Institutional Review Board, and written informed consent was obtained from adult patients or parents of minor patients in accordance with the Declaration of Helsinki.

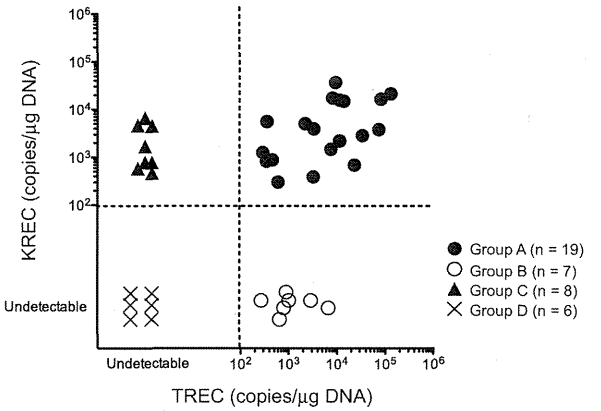

FIG 1. Quantifying TREC and KREC classifies patients with CVID into 4 groups. Patients with CVID were classified as follows: TREC(+)/KREC(+), group A (19 patients); TREC(+)/KREC(−), group B (7 patients); TREC(−)/KREC(+), group C (8 patients); and TREC(−)/KREC(−), group D (6 patients). *Undetectable,* Less than 100 copies/μg DNA.

Based on TREC and KREC copy numbers, the 40 patients with CVID were classified into 4 groups (groups A, B, C, and D; Fig 1). Comparing lymphocyte subsets, $CD3^+$ T-cell numbers were similar among groups A, B, and D but were significantly lower in group C ($P < .05$; group A, 1806 ± 204 cells/μL; group B, 1665 ± 430 cells/μL; group C, 517 ± 124 cells/μL; and group D, 1425 ± 724 cells/μL; $P = .0019$, Tukey multiple comparison test based on 1-way ANOVA). $CD3^+CD4^+CD45RO^+$ memory T-lymphocyte percentages in groups B, C, and D were significantly higher than those in group A ($P < .0001$; group A, 37% ± 16%; group B, 67% ± 13% [$P = .0006$]; group C, 92% ± 8.2% [$P < .0001$]; and group D: 83% ± 14% [$P < .0001$]; see Fig E1 in this article's Online Repository at www.jacionline.org); additionally, the percentages of these cells in groups C and D were higher than in group B ($P = .0115$). These results indicate that group C and D patients have markedly decreased $CD4^+CD45RA^+$ naive T-cell counts than group A patients and that counts in group B are also significantly decreased, although less so than in groups C or D, which is consistent with a report showing lower TREC copy numbers in $CD4^+CD45RO^+$ cells. Some patients in groups B, C, and D exhibited normal $CD4^+CD45RO^+$ percentages, although TREC levels, KREC levels, or both decreased. This discrepancy indicates that TREC/KREC levels could be independent markers to determine the patient's immunologic status in addition to $CD4^+CD45RA^+$; the reasons underlying the discrepancy between $CD4^+CD45RA^+$ and TREC/KREC levels remain unsolved.

$CD19^+$ B-cell numbers in group A were significantly higher ($P < .05$) than those in groups B and D (group A, 269 ± 65 cells/μL; group B, 35 ± 16 cells/μL; group C, 60 ± 11 cells/μL; and group D, 29 ± 16 cells/μL; $P = .0001$). However, B-cell subpopulations, including $CD27^-$, IgD^+CD27^+, and

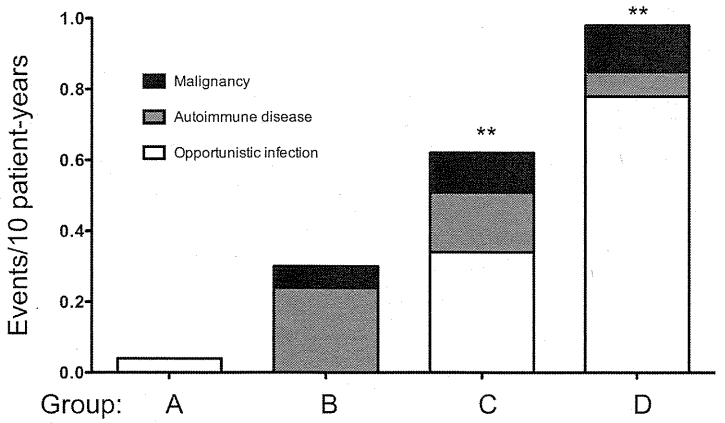

FIG 2. Cumulative incidence of complication events per 10 patient-years differs among groups. Opportunistic infections, autoimmune diseases, and malignancies were evaluated for each patient group. Complication incidences in group D (0.98 events/10 patient-years), group C (0.63 events/10 patient-years), and group B (0.30 events/10 patient-years) were higher than in group A (0.04 events/10 patient-years). Group A versus group D: $^{**}P = .0022$; group A versus C: $^{**}P = .0092$; group A vs group B: $P = .0692$.

IgD^-CD27^+ cells, were not significantly different among the groups. Standardizing KREC copy numbers for each patient by dividing their $CD19^+$ by their $CD27^+$ percentages revealed the same patient classification as that shown in Fig 1 (data not shown), indicating that the original classification was independent of $CD19^+$ B-cell or $CD27^+$ memory B-cell percentages.

Because TREC and KREC levels decrease with age (see Fig E2 in this article's Online Repository at www.jacionline.org)[5,6] and age distribution was wide in this study, we compared patients' ages among groups at the time of analysis to determine whether classification was associated with age. TREC/KREC-based classification was independent of both age and sex because age distribution was not significantly different among groups ($P > .05$; group A, 12.7 ± 2.3 years [2-30 years]; group B, 23.4 ± 4.2 years [6-39 years]; group C, 21.5 ± 6.1 years [4-52 years]; and group D, 25.5 ± 4.4 years [15-46 years]; data not shown) nor was male/female sex ratio (overall, 21/19; group A, 10/9; group B, 2/5; group C, 5/3; and group D, 4/2; $P = .4916$, χ^2 test; data not shown).

We next evaluated whether any correlation existed between TREC/KREC-based classification and clinical symptoms in each patient group. All patients in the study had been treated with intravenous immunoglobulin (IVIG) substitution at the time of analysis. We found that the cumulative events of complications (opportunistic infections, autoimmune diseases, and malignancies) per 10 patient-years were highest in group D (0.98 events/10 patient-years), followed by group C (0.63 events/10 patient-years), group B (0.30 events/10 patient-years), and group A (0.04 events/10 patient-years), where events in groups D and C were significantly higher than group A (group A vs group D, $P = .0022$; group A vs group C, $P = .0092$; group A vs group B, $P = .0692$; Fig 2). Furthermore, we found similar results when evaluating only patients 19 years old or older for group D (1.01 events/10 patient-years), group C (0.56 events/10 patient-years), group B (0.32 events/10 patient-years), and group A (0.06 events/10 patient-years; group A vs group D, $P = .0074$; group A vs group C, $P = .0407$; group A vs group B, $P = .1492$; data not shown). Categorizing patients by using several different previously reported CVID classifications (focused primarily on separating patients based on levels of circulating B-cell subsets), we found that no classification scheme showed any significant event increases in any particular group (see Fig E3 in this article's Online Repository at www.jacionline.org). Assessing longitudinal cumulative opportunistic infection incidence among the groups, group D and C values were significantly higher than in group A (see Fig E4, A, in this article's Online Repository at www.jacionline.org; $P = .0059$). Autoimmune and malignant diseases ($P = .5168$ and $P = .6900$, respectively) were observed in groups B and D but not in group A (see Fig E4, *B* and *C*). Cumulative events were significantly different between groups ($P = .0313$, log-rank test; group A, 5.3% and 5.3%; group B, 14.3% and 57.1%; group C, 27.1% and 63.5%; and group D, 33.3% and 83.3% at 10 and 30 years of age, respectively; see Fig E4, *D*). One patient in group D died of *Pneumocystis jirovecii* pneumonia, and 2 other patients in the same group received hematopoietic stem cell transplantation after complications caused by EBV-related lymphoproliferative disorder.

Assessing these data, TREC/KREC-based classification matches clinical outcomes. Because group D patients exhibited the most frequent complications (opportunistic infections, autoimmune diseases, and malignancies), they could receive a diagnosis of CID based on these symptoms. If they are indeed determined to have CID, then TREC/KREC analysis is helpful to distinguish between CID and CVID. Their TREC(−)/KREC(−) phenotype might relate to defective V(D)J recombination in T- and B-cell development[8] because patients with B-negative SCID (*RAG1*, *RAG2*, *Artemis*, and *LIG4*), as well as patients with ataxia-telangiectasia (AT) and Nijmegen breakage syndrome (NBS; see Fig E5 in this article's Online Repository at www.jacionline.org),[5,6] were also negative for both TREC and KREC; it is intriguing to speculate that an unknown V(D)J recombination gene or genes is responsible. As for treatment, hematopoietic stem cell transplantation should be considered the preferred treatment to "cure" group D patients, as reported in patients with severe CVID/CID, because event-free survival is poor.[9]

In contrast to group D patients, TREC(+)/KREC(+) group A patients treated with IVIG substitution therapy remained healthy. One possible explanation is that these patients harbor

defects only in terminal B-cell differentiation, but not in T cells, and represent typical patients with CVID, as originally reported.

Group C patients had a high frequency of both opportunistic infections and malignancies, suggesting that these TREC(−) patients have T-cell defects. Although group C patients had a similar TREC/KREC pattern to patients with SCID with B cells (*IL2RG* and *JAK3*; see Fig E5, *A*), they do not fulfill the European Society for Immunodeficiencies criteria for SCID, and no mutation was identified in the SCID genes estimated from clinical manifestation and lymphocyte subset analysis. However, from our data, they would likely benefit from undergoing similar treatment to patients with SCID or CID to prevent these complications.

Although opportunistic infections were rare in group B patients, autoimmune diseases were often observed. This is consistent with this group being TREC(+)/KREC(−) and the idea that balance between T and B cells is important to prevent autoimmune diseases in patients with CVID.[1] Intriguingly, a group of patients with AT and NBS were also TREC(+)/KREC(−) (see Fig E4, *B*), which is similar to group B patients. Additionally, $CD45RA^+CD4^+$ naive T-cell numbers were reduced in most group B patients, which is similar to the phenotype exhibited by patients with AT and NBS. This finding raises the possibility that although some group B patients are also T-cell deficient, as well as B-cell deficient, and should be treated similarly to patients with CID, other patients have only B-cell deficiency and are effectively treated with IVIG substitution therapy.

By analyzing a large CVID patient cohort, the overall survival rate of patients with more than 1 complication was worse than that for patients without other complications.[4] Our findings indicate that low TREC levels, KREC levels, or both are useful markers that correlate well with the overall survival rate in patients with CVID. Therefore we conclude that TREC and KREC are useful markers to assess the clinical severity and pathogenesis of each patient with CVID and to distinguish CID from CVID. Thus patient classification based on TREC/KREC levels would provide a helpful tool for deciding on an effective treatment plan for each patient with CVID.

We thank the following doctors who contributed patient data to this study: Satoshi Okada, Kazuhiro Nakamura, Masao Kobayashi, Tomoyuki Mizukami, Yoshitora Kin, Hironobu Yamaga, Shinsuke Yamada, Kazuhide Suyama, Chihiro Kawakami, Yuko Yoto, Kensuke Oryoji, Ayumu Itoh, Takao Tsuji, Daisuke Imanishi, Yutaka Tomishima, Minako Tomiita, Kaori Sasaki, Akira Ohara, Hanako Jimi, Mayumi Ono, Daisuke Hori, Yuichi Nakamura, Yoshitoshi Otsuka, Toshiyuki Kitoh, Toshio Miyawaki, Akihiko Maeda, Terumasa Nagase, Takahiro Endo, Yoshiaki Shikama, Mikiya Endo, Satoru Kumaki, Lennart Hammarström, Janine Reichenbach, and Reinhard Seger. x10^3 copies/µg DNA

FIG E2. KREC levels were analyzed in genomic DNA samples extracted from peripheral blood of control subjects at different age groups (n = 158; age range, 1 month to 55 years). KREC levels were significantly higher in infants (17.9 ± 3.9 × 10^3 copies/µg DNA) compared with other children's age groups (8.9 ± 1.3 × 10^3 copies/µg DNA in the 1- to 6-year-old group and 3.6 ± 3.8 × 10^3 copies/µg DNA in the 7- to 18-year-old group) and adults (2.0 ± 3.3 × 10^3 copies/µg DNA; $P < .0001$).

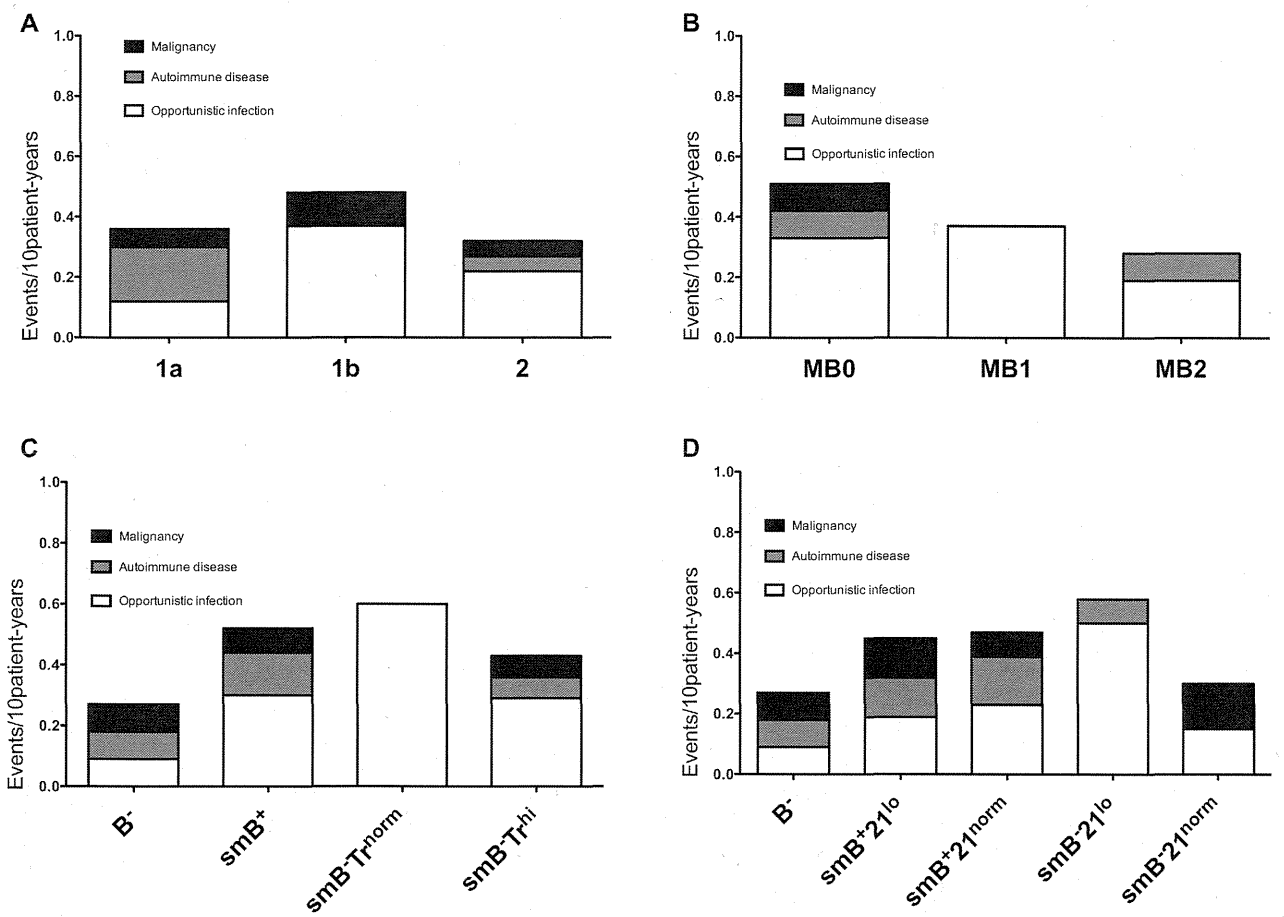

FIG E3. Patients were classified in the following way and analyzed for cumulative incidence of complications: **A,** Freiburg; **B,** Paris; and **C,** EUROclass classifications, according to $CD38^{hi}IgM^{hi}$ transitional B cells (Fig E3, *A-C*) or $CD21^{low}$ B cells **(D)**. Five patients were excluded from the Freiburg and Paris classifications because of decreased B-cell numbers (<1%). Additionally, we excluded 4 patients in the Freiburg classification, 1 patient in the Paris classification, and 4 patients in the EUROclass classification for transitional B cells and 8 in the EUROclass classification for $CD21^{low}$ B cells because of lack of data. The following cumulative events/10 patient-years were found. Freiburg classification: 1a, 0.36; 1b, 0.48; 2, 0.32. Paris classification: MB0, 0.50; MB1, 0.37; MB2, 0.28. EUROclass classification according to transitional B cells: B^-, 0.27; smB^+, 0.52; smB^-Tr^{norm}, 0.60; smB^-Tr^{high}, 0.43. EUROclass classification according to $CD21^{lo}$ B cells: B^-, 0.27; smB^+21^{lo}, 0.45; smB^+21^{norm}, 0.47; smB^-21^{lo}, 0.58; smB^-21^{norm}, 0.30. No classification showed any significantly increased events in any particular group according to calculated *P* values, as follows—Freiburg classification: 1a vs 2 = .898, 1b vs 2 = .479, 1a vs 1b = .838; Paris classification: MB0 vs MB2 = .179, MB1 vs MB2 = .654, MB0 vs MB1 = .764; EUROclass classification according to transitional B cells: B^- vs smB^+ = .298, smB^-Tr^{norm} vs smB^+ = .809, smB^-Tr^{hi} vs smB^+ = .702, smB^-Tr^{hi} vs smB^-Tr^{norm} = .641, smB^-Tr^{norm} vs B^- = .329, smB^-Tr^{hi} vs B^- = .508; EUROclass classification according to $CD21^{lo}$ B cells: B^- vs smB^+21^{norm} = .443, smB^+21^{lo} vs smB^+21^{norm} = .930, smB^-21^{lo} vs smB^+21^{norm} = .695, smB^-21^{norm} vs smB^+21^{norm} = .575, B^- vs smB^-21^{norm} = .926, smB^+21^{lo} vs smB^-21^{norm} = .609, smB^-21^{lo} vs smB^-21^{norm} = .399, B^- vs smB^+21^{lo} = 0.474, B^- vs smB^-21^{lo} = 0.270, smB^+21^{lo} vs smB^-21^{lo} = 0.618.

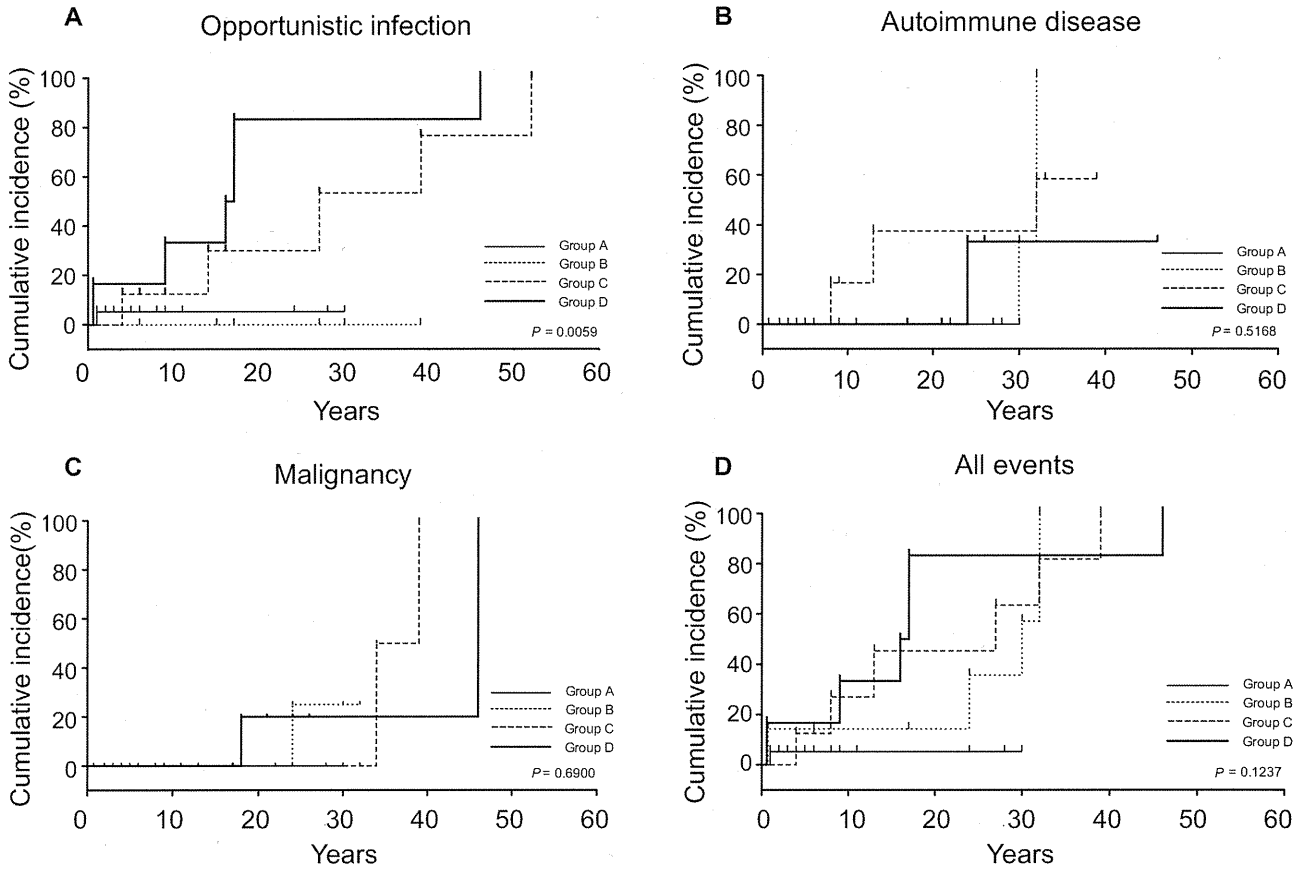

FIG E4. Comparing longitudinal cumulative incidence of complication events among groups. Cumulative incidence was estimated separately and longitudinally by using the Kaplan-Meier method and statistically compared between groups by using the log-rank test. The cumulative incidence of opportunistic infections **(A)**, autoimmune diseases **(B)**, malignancies **(C)**, and all events **(D)** is shown.

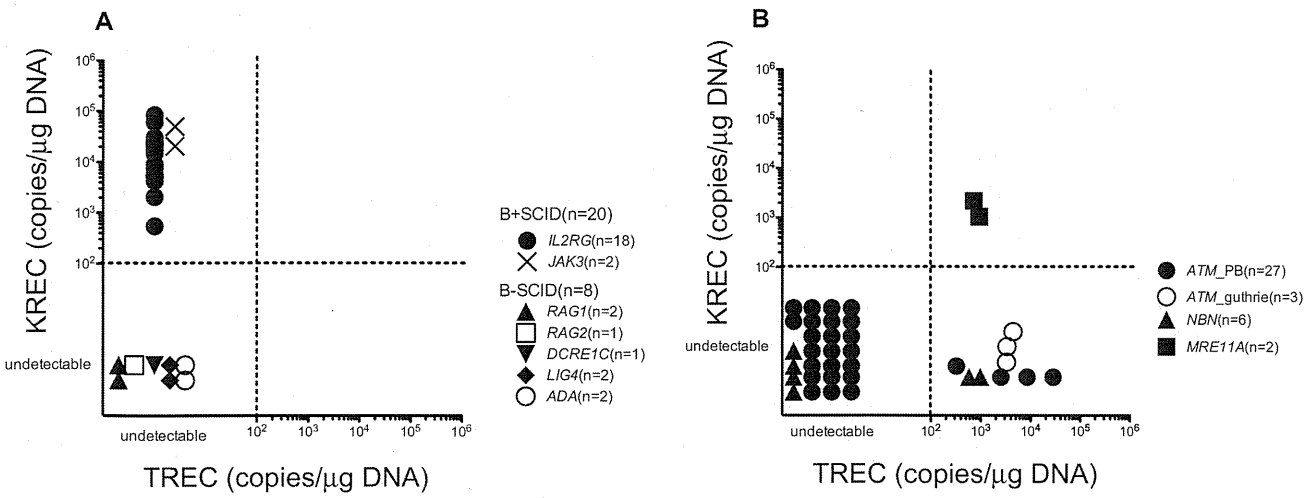

FIG E5. TREC and KREC quantification classifies patients with SCID, AT, NBS, or ataxia-telangiectasia–like disease *(ATLD)* into 4 groups. **A,** Patients with B^+SCID (n = 20) were classified as group C, and patients with B^-SCID (n = 8) were classified as group D; these patients were included in the previous studies.[5,6] **B,** Although most patients with AT (n = 23) and patients with NBS (n = 4) were classified as group D, TRECs were detected in peripheral blood samples (n = 4 in patients with AT and n = 2 in patients with NBS) and neonatal Guthrie cards (n = 3) of some patients with AT, who were classified as group B. Patients with ATLD with *MRE11A* mutations were classified as group A.

In the United States the regulation of nonstandardized AEs presented some similarities with our approach. AEs were classified into 4 categories according to scientific data supporting their use in diagnosis and treatment, and the extracts were regularly evaluated by the regulatory agencies. The last update was conducted between 2003 and 2011, and the process was recently reviewed by Slater et al.[1] It was shown that for nearly half of nonstandardized AEs there were, in fact, little or no data to support their effectiveness. We had similar results: 66 of 84 AEs were validated for diagnosis, but only for 29 of 66 was there at least 1 published piece of data to support their effectiveness for immunotherapy (Table I). Among those 66 authorized AEs, approximately one third are standardized. There is no consensus about the standardization methods, and the European approaches present some differences compared with the US approach (see Table E1 in this article's Online Repository at www.jacionline.org). Briefly, in-house reference preparation (IHRP) AEs are standardized *in vivo* and *in vitro*. Each manufacturer has its own IHRP, and there is no national standard. Batch-to-batch standardization is performed *in vitro* through a comparison of the AEs with the IHRP.[9]

In the future, the NPP list will be updated every 5 years, and requests for MA will be made and processed for standardized AEs produced industrially and frequently used for immunotherapy.

In conclusion, for the first time in Europe, this work guarantees that available AEs are clinically relevant and safe. Moreover, it guarantees that all AEs comply with recent European guidelines on APs, including rare allergens for which it is not possible to obtain large clinical studies requested for MA. The process involved all the representatives of allergists and manufacturers and is still ongoing.

Common variable immunodeficiency classification by quantifying T-cell receptor and immunoglobulin κ-deleting recombination excision circles

To the Editor:

Common variable immunodeficiency (CVID) is the most frequent primary immunodeficiency associated with hypogammaglobulinemia and other various clinical manifestations. CVID was originally reported to be a disease primarily caused by defective B-cell function, with defective terminal B-cell differentiation rendering B cells unable to produce immunoglobulin. However, combined immunodeficiency (CID) involving both defective B and T cells is often misdiagnosed as CVID.[1] Indeed, one study reported that $CD4^+$ T-cell numbers were decreased in 29% of 473 patients with CVID[2]; similarly, another study found that naive T-cell numbers were markedly reduced in 44% (11/25) of patients with CVID.[3] These observations indicated that a subgroup of patients with clinically diagnosed CVID is T-cell deficient. Consistently, some patients with CVID have complications that might be related to T-cell deficiency, including opportunistic infections, autoimmune diseases, and malignancies, which is similar to that observed in patients with CID.[1,4] Therefore identifying novel markers to better classify CVID and distinguish CID from CVID will be required to best manage medical treatment for CVID.

We recently performed real-time PCR-based quantification of T-cell receptor excision circles (TREC) and signal joint immunoglobulin κ-deleting recombination excision circles (KREC) for mass screening of severe combined immunodeficiency (SCID)[5] and B-lymphocyte deficiency[6] in neonates. TREC and KREC are associated with T-cell and B-cell neogenesis, respectively.[7] Here we retrospectively report that TREC and KREC are useful for classifying patients with clinically diagnosed CVID.

Hypogammaglobulinemic patients (n = 113) were referred to our hospital for immunodeficiency from 2005-2011, and the following patients were excluded from the CVID pool by estimating their SCID genes based on clinical manifestations and lymphocyte subset analysis: 18 patients with SCID diagnoses; 14 patients less than 2 years of age (transient infantile hypogammaglobulinemia); 10 patients with IgM levels of greater than 100 mg/dL (hyper-IgM syndrome); 26 patients with diseases other than CVID caused by known gene alterations (10 with X-linked agammaglobulinemia and 11 with hyper-IgM syndrome

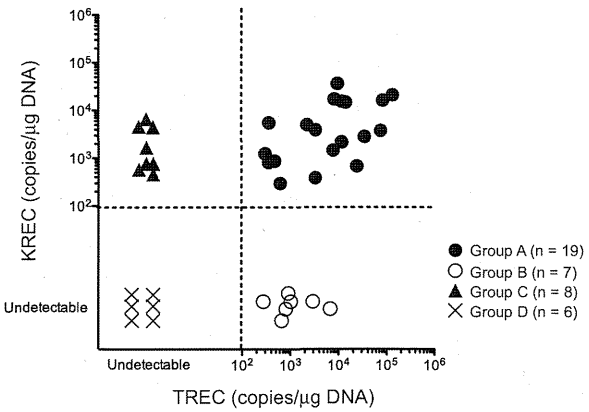

FIG 1. Quantifying TREC and KREC classifies patients with CVID into 4 groups. Patients with CVID were classified as follows: TREC(+)/KREC(+), group A (19 patients); TREC(+)/KREC(−), group B (7 patients); TREC(−)/KREC(+), group C (8 patients); and TREC(−)/KREC(−), group D (6 patients). *Undetectable*, Less than 100 copies/μg DNA.

[*CD40L* or *AICDA* mutated]), (2 with DiGeorge syndrome, and 3 with *FOXP3*, *IKBKG*, or *6p* deletions); and 5 patients with drug-induced hypogammaglobulinemia. The remaining 40 patients with decreased IgG (≥2 SDs below the mean for age), IgM, and/or IgA levels, as well as absent isohemagglutinins, poor response to vaccines, or both were included in this study as patients with CVID and analyzed for TREC/KREC levels, retrospectively.

Ages of patients with CVID ranged from 2 to 52 years (median age, 15.5 years). The sex ratio of the patients was 21 male/19 female patients. Serum IgG, IgA, and IgM levels were 370 ± 33 mg/dL (0-716 mg/dL), 30 ± 7 mg/dL (1-196 mg/dL), and 40 ± 6 mg/dL (2-213 mg/dL), respectively. TREC and KREC quantification was performed by using DNA samples extracted from peripheral blood, as reported previously.[5,6] Clinical symptoms were then assessed retrospectively. The study protocol was approved by the National Defense Medical College Institutional Review Board, and written informed consent was obtained from adult patients or parents of minor patients in accordance with the Declaration of Helsinki.

Based on TREC and KREC copy numbers, the 40 patients with CVID were classified into 4 groups (groups A, B, C, and D; Fig 1). Comparing lymphocyte subsets, $CD3^+$ T-cell numbers were similar among groups A, B, and D but were significantly lower in group C ($P < .05$; group A, 1806 ± 204 cells/μL; group B, 1665 ± 430 cells/μL; group C, 517 ± 124 cells/μL; and group D, 1425 ± 724 cells/μL; $P = .0019$, Tukey multiple comparison test based on 1-way ANOVA). $CD3^+CD4^+CD45RO^+$ memory T-lymphocyte percentages in groups B, C, and D were significantly higher than those in group A ($P < .0001$; group A, 37% ± 16%; group B, 67% ± 13% [$P = .0006$]; group C, 92% ± 8.2% [$P < .0001$]; and group D: 83% ± 14% [$P < .0001$]; see Fig E1 in this article's Online Repository at www.jacionline.org); additionally, the percentages of these cells in groups C and D were higher than in group B ($P = .0115$). These results indicate that group C and D patients have markedly decreased $CD4^+CD45RA^+$ naive T-cell counts than group A patients and that counts in group B are also significantly decreased, although less so than in groups C or D, which is consistent with a report showing lower TREC copy numbers in $CD4^+CD45RO^+$ cells. Some patients in groups B, C, and D exhibited normal $CD4^+CD45RO^+$ percentages, although TREC levels, KREC levels, or both decreased. This discrepancy indicates that TREC/KREC levels could be independent markers to determine the patient's immunologic status in addition to $CD4^+CD45RA^+$; the reasons underlying the discrepancy between $CD4^+CD45RA^+$ and TREC/KREC levels remain unsolved.

$CD19^+$ B-cell numbers in group A were significantly higher ($P < .05$) than those in groups B and D (group A, 269 ± 65 cells/μL; group B, 35 ± 16 cells/μL; group C, 60 ± 11 cells/μL; and group D, 29 ± 16 cells/μL; $P = .0001$). However, B-cell subpopulations, including $CD27^-$, IgD^+CD27^+, and IgD^-CD27^+ cells, were not significantly different among the groups. Standardizing KREC copy numbers for each patient by dividing their $CD19^+$ by their $CD27^+$ percentages revealed the same patient classification as that shown in Fig 1 (data not shown), indicating that the original classification was independent of $CD19^+$ B-cell or $CD27^+$ memory B-cell percentages.

Because TREC and KREC levels decrease with age (see Fig E2 in this article's Online Repository at www.jacionline.org)[5,6] and age distribution was wide in this study, we compared patients' ages among groups at the time of analysis to determine whether classification was associated with age. TREC/KREC-based classification was independent of both age and sex because age distribution was not significantly different among groups ($P > .05$; group A, 12.7 ± 2.3 years [2-30 years]; group B, 23.4 ± 4.2 years [6-39 years]; group C, 21.5 ± 6.1 years [4-52 years]; and group D, 25.5 ± 4.4 years [15-46 years]; data not shown) nor was male/female sex ratio (overall, 21/19; group A, 10/9; group B, 2/5; group C, 5/3; and group D, 4/2; $P = .4916$, χ^2 test; data not shown).

We next evaluated whether any correlation existed between TREC/KREC-based classification and clinical symptoms in each patient group. All patients in the study had been treated with intravenous immunoglobulin (IVIG) substitution at the time of analysis. We found that the cumulative events of complications (opportunistic infections, autoimmune diseases, and malignancies) per 10 patient-years were highest in group D (0.98 events/10 patient-years), followed by group C (0.63 events/10 patient-years), group B (0.30 events/10 patient-years), and group A (0.04 events/10 patient-years), where events in groups D and C were significantly higher than group A (group A vs group D, $P = .0022$; group A vs group C, $P = .0092$; group A vs group B, $P = .0692$; Fig 2). Furthermore, we found similar results when evaluating only patients 19 years old or older for group D (1.01 events/10 patient-years), group C (0.56 events/10 patient-years), group B (0.32 events/10 patient-years), and group A (0.06 events/10 patient-years; group A vs group D, $P = .0074$; group A vs group C, $P = .0407$; group A vs group B, $P = .1492$; data not shown). Categorizing patients by using several different previously reported CVID classifications (focused primarily on separating patients based on levels of circulating B-cell subsets), we found that no classification scheme showed any significant event increases in any particular group (see Fig E3 in this article's Online Repository at www.jacionline.org). Assessing longitudinal cumulative opportunistic infection incidence among the groups, group D and C values were significantly higher than in group A (see Fig E4, *A*, in this article's Online Repository at www.jacionline.org; $P = .0059$). Autoimmune and malignant diseases ($P = .5168$ and $P = .6900$, respectively) were observed in groups B and D but not in group A (see Fig E4, *B* and *C*). Cumulative events were significantly different between groups ($P = .0313$, log-rank test; group A, 5.3% and 5.3%; group B, 14.3% and

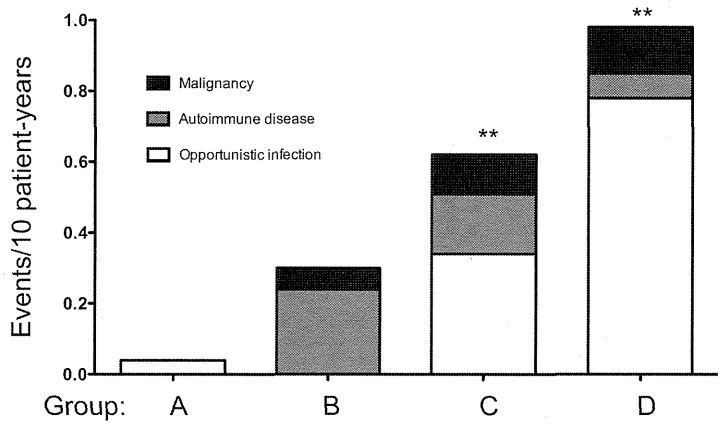

FIG 2. Cumulative incidence of complication events per 10 patient-years differs among groups. Opportunistic infections, autoimmune diseases, and malignancies were evaluated for each patient group. Complication incidences in group D (0.98 events/10 patient-years), group C (0.63 events/10 patient-years), and group B (0.30 events/10 patient-years) were higher than in group A (0.04 events/10 patient-years). Group A versus group D: $^{**}P = .0022$; group A versus C: $^{**}P = .0092$; group A vs group B: $P = .0692$.

57.1%; group C, 27.1% and 63.5%; and group D, 33.3% and 83.3% at 10 and 30 years of age, respectively; see Fig E4, *D*). One patient in group D died of *Pneumocystis jirovecii* pneumonia, and 2 other patients in the same group received hematopoietic stem cell transplantation after complications caused by EBV-related lymphoproliferative disorder.

Assessing these data, TREC/KREC-based classification matches clinical outcomes. Because group D patients exhibited the most frequent complications (opportunistic infections, autoimmune diseases, and malignancies), they could receive a diagnosis of CID based on these symptoms. If they are indeed determined to have CID, then TREC/KREC analysis is helpful to distinguish between CID and CVID. Their TREC(−)/KREC(−) phenotype might relate to defective V(D)J recombination in T- and B-cell development[8] because patients with B-negative SCID (*RAG1*, *RAG2*, *Artemis*, and *LIG4*), as well as patients with ataxia-telangiectasia (AT) and Nijmegen breakage syndrome (NBS; see Fig E5 in this article's Online Repository at www.jacionline.org),[5,6] were also negative for both TREC and KREC; it is intriguing to speculate that an unknown V(D)J recombination gene or genes is responsible. As for treatment, hematopoietic stem cell transplantation should be considered the preferred treatment to "cure" group D patients, as reported in patients with severe CVID/CID, because event-free survival is poor.[9]

In contrast to group D patients, TREC(+)/KREC(+) group A patients treated with IVIG substitution therapy remained healthy. One possible explanation is that these patients harbor defects only in terminal B-cell differentiation, but not in T cells, and represent typical patients with CVID, as originally reported.

Group C patients had a high frequency of both opportunistic infections and malignancies, suggesting that these TREC(−) patients have T-cell defects. Although group C patients had a similar TREC/KREC pattern to patients with SCID with B cells (*IL2RG* and *JAK3*; see Fig E5, *A*), they do not fulfill the European Society for Immunodeficiencies criteria for SCID, and no mutation was identified in the SCID genes estimated from clinical manifestation and lymphocyte subset analysis. However, from our data, they would likely benefit from undergoing similar treatment to patients with SCID or CID to prevent these complications.

Although opportunistic infections were rare in group B patients, autoimmune diseases were often observed. This is consistent with this group being TREC(+)/KREC(−) and the idea that balance between T and B cells is important to prevent autoimmune diseases in patients with CVID.[1] Intriguingly, a group of patients with AT and NBS were also TREC(+)/KREC(−) (see Fig E4, *B*), which is similar to group B patients. Additionally, $CD45RA^{+}CD4^{+}$ naive T-cell numbers were reduced in most group B patients, which is similar to the phenotype exhibited by patients with AT and NBS. This finding raises the possibility that although some group B patients are also T-cell deficient, as well as B-cell deficient, and should be treated similarly to patients with CID, other patients have only B-cell deficiency and are effectively treated with IVIG substitution therapy.

By analyzing a large CVID patient cohort, the overall survival rate of patients with more than 1 complication was worse than that for patients without other complications.[4] Our findings indicate that low TREC levels, KREC levels, or both are useful markers that correlate well with the overall survival rate in patients with CVID. Therefore we conclude that TREC and KREC are useful markers to assess the clinical severity and pathogenesis of each patient with CVID and to distinguish CID from CVID. Thus patient classification based on TREC/KREC levels would provide a helpful tool for deciding on an effective treatment plan for each patient with CVID.

We thank the following doctors who contributed patient data to this study: Satoshi Okada, Kazuhiro Nakamura, Masao Kobayashi, Tomoyuki Mizukami, Yoshitora Kin, Hironobu Yamaga, Shinsuke Yamada, Kazuhide Suyama, Chihiro Kawakami, Yuko Yoto, Kensuke Oryoji, Ayumu Itoh, Takao Tsuji, Daisuke Imanishi, Yutaka Tomishima, Minako Tomiita, Kaori Sasaki, Akira Ohara, Hanako Jimi, Mayumi Ono, Daisuke Hori, Yuichi Nakamura, Yoshitoshi Otsuka, Toshiyuki Kitoh, Toshio Miyawaki, Akihiko Maeda, Terumasa Nagase, Takahiro Endo, Yoshiaki Shikama, Mikiya Endo, Satoru Kumaki, Lennart Hammarström, Janine Reichenbach, and Reinhard Seger. We also thank Professor Junichi Yata for critical reading and Ms Kaori Tomita, Ms Kimiko Gasa, and Ms Atsuko Kudo for their skillful technical assistance.

Homing frequency of human T cells inferred from peripheral blood depletion kinetics after sphingosine-1-phosphate receptor blockade

To the Editor:

Naive and central memory (CM) T cells home through lymph nodes (LNs), whereas T cells with an effector memory (EM) phenotype preferentially screen peripheral tissues in search of cognate antigen.[1] LN entry and egress are distinct and highly regulated processes mediated by an orchestrated interplay of chemokines/chemokine receptors and adhesion molecules.[2] Interaction of peripheral node addressins with L-selectin on T cells allows tethering/rolling along high endothelial venules (HEVs).[2] Interaction of the chemokine receptor CCR7 with its ligands CCL19/CCL21 and CXCR4 with CXCL12 then mediates firm adhesion to HEVs through high-affinity interactions of lymphocyte function–associated antigen 1 and intercellular adhesion molecule 1, permitting transmigration of T cells across the HEV cell layer.[2] Within the LNs, T-cell migration is directed through T-cell zones toward the cortical sinuses.[3] A sphingosine-1-phosphate (S1P) gradient established across the endothelial cells of the cortical sinuses is directing LN egress of T cells through efferent lymph back to the peripheral blood circulation.[4] Acting as a functional antagonist on the S1P receptor, the pharmacologic compound fingolimod, which has shown efficacy in the treatment of multiple sclerosis (MS), blocks this egress.[4,5] As a consequence, in fingolimod-treated subjects naive and CM T cells are trapped in LNs and reduced in the blood circulation.[6]

Here, by studying depletion kinetics of T cells in the blood of *de novo* fingolimod-exposed subjects in combination with *in vitro* migration experiments, homing frequencies and LN access hierarchy between T-cell subsets were derived indirectly. First, we defined the effect of *de novo* fingolimod exposure on the number of circulating $CD4^+$ and $CD8^+$ phenotypic T-cell subsets in patients with MS during a 6-hour observation period (hourly measurements, 1 time before and 6 times after drug exposure) by using flow cytometry (detailed information on patients and methods is provided in the Methods section and Table E1 in this article's Online Repository at www.jacionline.org). In fingolimod-treated subjects, 6 hours after the first drug dose, numbers of $CD4^+$ T-cell subsets with an LN homing phenotype (ie, naive and CM T cells) were significantly reduced (Fig 1, *A* [representative example; absolute cell counts], and Fig 1, *B* [pooled data; proportional change]). Intriguingly, the kinetics of reduction differed between phenotypic naive (CD62 ligand [CD62L]–positive $CD45RA^+$) and CM ($CD62L^+CD45RA^-$) $CD4^+$ T cells. Specifically, compared with baseline measurements, naive $CD4^+$ T-cell counts started to decrease earlier than CM $CD4^+$ T-cell counts (2 vs 5 hours after fingolimod exposure; Fig 1, *B*). In $CD8^+$ T cells, contrasting $CD4^+$ T cells, only naive ($CD62L^+CD45RA^+$) $CD8^+$ T-cell counts decreased significantly (after 3 vs 2 hours in naive $CD4^+$ T cells) after the first dose of fingolimod (Fig 1, *C* [representative example; absolute cell counts], and Fig 1, *D* [pooled data; proportional change]).

On the basis of these *ex vivo* depletion kinetics, *in vitro* chemotaxis experiments were performed, as described in the Methods section in this article's Online Repository. In a transwell system spontaneous migration of bulk $CD4^+$ and $CD8^+$ T cells was comparably low in healthy control subjects and untreated patients with MS (and was further decreased in the presence of fingolimod; see Fig E1 in this article's Online Repository at www.jacionline.org). Gradients of CXCL12, CCL19, and CCL21 mediated a clear increase in migration of bulk $CD4^+$ and $CD8^+$ T cells from healthy control subjects and untreated patients with MS, which was not significantly influenced by fingolimod (see Fig E1). Dot plot distribution (as a percentage) of migrated versus nonmigrated, phenotypic naive, CM, EM, and (for $CD8^+$ T cells) CD45RA re-expressing EM cells (EMRA) was then compared between control cells (spontaneous migration) and cells that migrated toward CXCL12, CCL19, or CCL21. An example of CXCL12-mediated changes in the

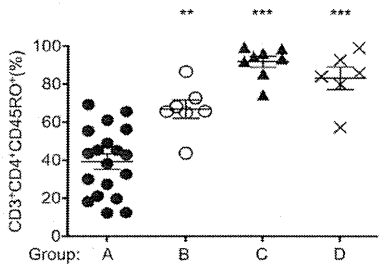

FIG E1. $CD45RO^+CD3^+CD4^+$ T-cell frequency within $CD4^+CD3^+$ lymphocytes was analyzed among groups. $CD45RO^+CD3^+CD4^+$ lymphocyte counts were significantly higher in groups B, C, and D compared with those in group A ($P < .0001$). Group A: 37% ± 16%; group B: 67% ± 13% (**$P < .01$); group C: 92% ± 8.2% (***$P < .001$); and group D: 83% ± 14% (***$P < .001$).

mean:	17.9	8.9	3.6	2.0	
max:	442	349	12.1	12.0	x10³ copies/µg DNA
min:	2.8	0.99	0.29	0.22	

FIG E2. KREC levels were analyzed in genomic DNA samples extracted from peripheral blood of control subjects at different age groups (n = 158; age range, 1 month to 55 years). KREC levels were significantly higher in infants (17.9 ± 3.9 × 10^3 copies/µg DNA) compared with other children's age groups (8.9 ± 1.3 × 10^3 copies/µg DNA in the 1- to 6-year-old group and 3.6 ± 3.8 × 10^3 copies/µg DNA in the 7- to 18-year-old group) and adults (2.0 ± 3.3 × 10^3 copies/µg DNA; $P < .0001$).

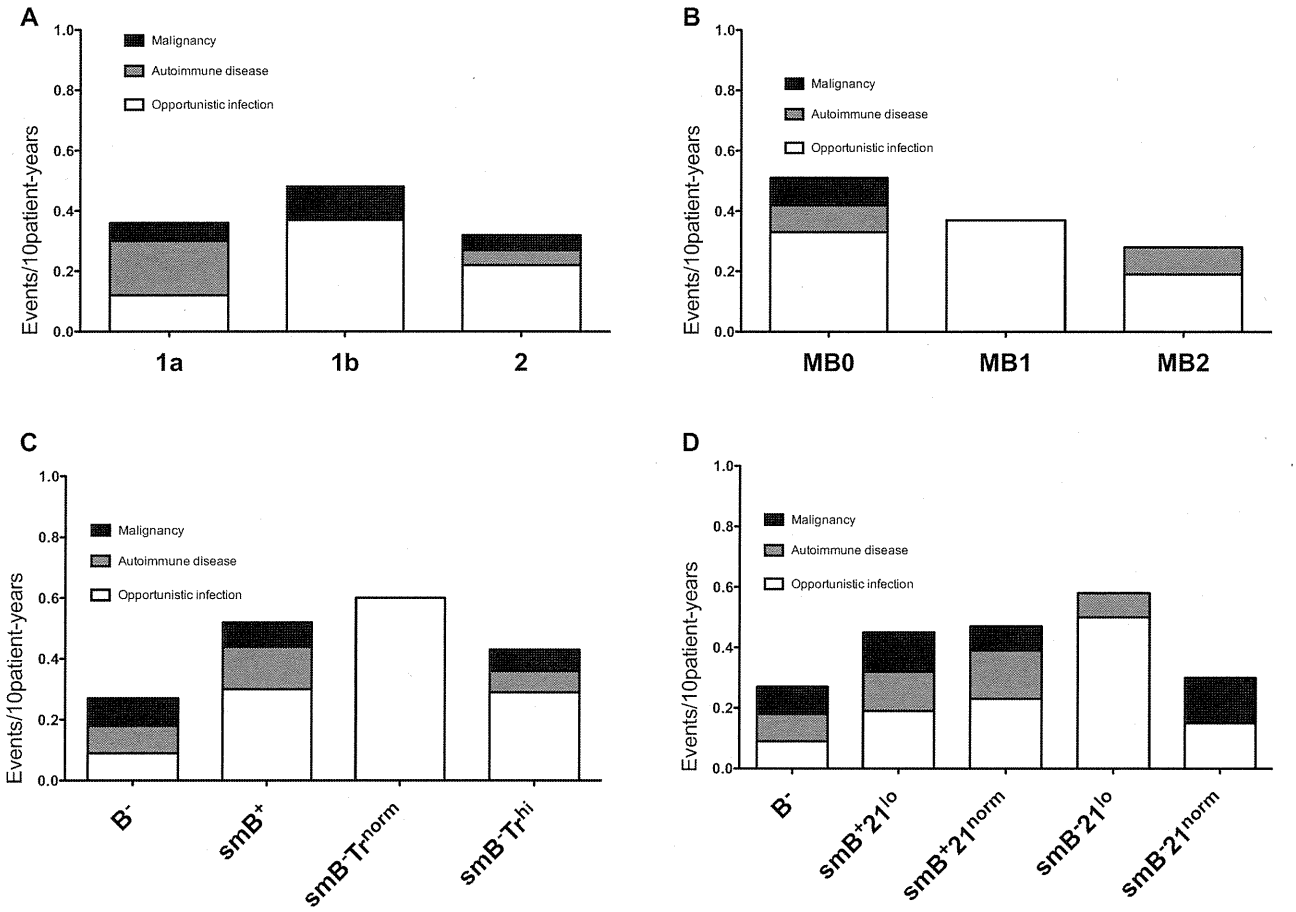

FIG E3. Patients were classified in the following way and analyzed for cumulative incidence of complications: **A,** Freiburg; **B,** Paris; and **C,** EUROclass classifications, according to $CD38^{hi}IgM^{hi}$ transitional B cells (Fig E3, *A-C*) or $CD21^{low}$ B cells **(D)**. Five patients were excluded from the Freiburg and Paris classifications because of decreased B-cell numbers (<1%). Additionally, we excluded 4 patients in the Freiburg classification, 1 patient in the Paris classification, and 4 patients in the EUROclass classification for transitional B cells and 8 in the EUROclass classification for $CD21^{low}$ B cells because of lack of data. The following cumulative events/10 patient-years were found. Freiburg classification: 1a, 0.36; 1b, 0.48; 2, 0.32. Paris classification: MB0, 0.50; MB1, 0.37; MB2, 0.28. EUROclass classification according to transitional B cells: B^-, 0.27; smB^+, 0.52; smB^-Tr^{norm}, 0.60; smB^-Tr^{high}, 0.43. EUROclass classification according to $CD21^{lo}$ B cells: B^-, 0.27; smB^+21^{lo}, 0.45; smB^+21^{norm}, 0.47; smB^-21^{lo}, 0.58; smB^-21^{norm}, 0.30. No classification showed any significantly increased events in any particular group according to calculated *P* values, as follows—Freiburg classification: 1a vs 2 = .898, 1b vs 2 = .479, 1a vs 1b = .838; Paris classification: MB0 vs MB2 = .179, MB1 vs MB2 = .654, MB0 vs MB1 = .764; EUROclass classification according to transitional B cells: B^- vs smB^+ = .298, smB^-Tr^{norm} vs smB^+ = .809, smB^-Tr^{hi} vs smB^+ = .702, smB^-Tr^{hi} vs smB^-Tr^{norm} = .641, smB^-Tr^{norm} vs B^- = .329, smB^-Tr^{hi} vs B^- = .508; EUROclass classification according to $CD21^{lo}$ B cells: B^- vs smB^+21^{norm} = .443, smB^+21^{lo} vs smB^+21^{norm} = .930, smB^-21^{lo} vs smB^+21^{norm} = .695, smB^-21^{norm} vs smB^+21^{norm} = .575, B^- vs smB^-21^{norm} = .926, smB^+21^{lo} vs smB^-21^{norm} = .609, smB^-21^{lo} vs smB^-21^{norm} = .399, B^- vs smB^+21^{lo} = 0.474, B^- vs smB^-21^{lo} = 0.270, smB^+21^{lo} vs smB^-21^{lo} = 0.618.

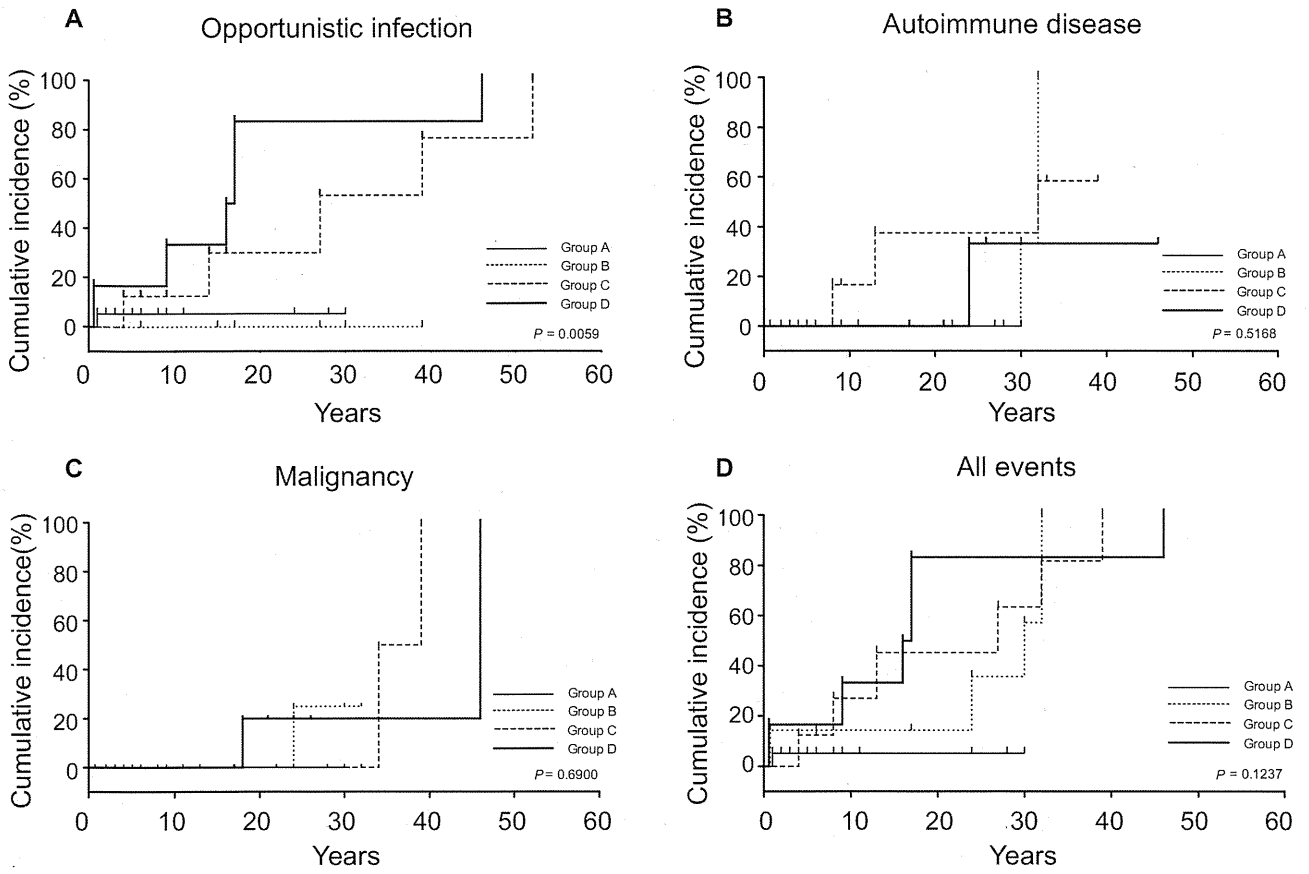

FIG E4. Comparing longitudinal cumulative incidence of complication events among groups. Cumulative incidence was estimated separately and longitudinally by using the Kaplan-Meier method and statistically compared between groups by using the log-rank test. The cumulative incidence of opportunistic infections **(A)**, autoimmune diseases **(B)**, malignancies **(C)**, and all events **(D)** is shown.
