even lower in the N subpopulation derived from asymptomatic carriers and indolent/acute ATLs (Fig. 6A). In addition, examination of *Helios* mRNA transcript variants revealed that expression levels of *Hel-2*, which lacks part of exon 3, were upregulated in the D and N subpopulations of asymptomatic carriers and indolent ATLs, and it was dominantly expressed in the N subpopulation of acute ATLs (Fig. 6B).

Supplementary Fig. S5 presents a summary of this study. The representative flow-cytometric profile shows how the CADM1 versus CD7 plot reflects disease progression in HTLV-I infection. The plot together with the gene expression profiles clearly distinguished the subpopulations of distinct oncogenic stages. The groups classified according to gene expression profile are shown as blue, yellow, and red and are superimposed on the CADM1 versus CD7 plot. Collectively, our data suggest that CADM1 expression and stepwise downregulation of CD7 were closely associated with clonal expansion of HTLV-I–infected cells in ATL progression.

Discussion

We showed that the CADM1 versus CD7 plot is capable of discriminating clonally expanding HTLV-I–infected cells in indolent ATLs and even in asymptomatic carriers, as well as in acute-type ATLs. Our analysis demonstrated efficient enrichment of HTLV-I–infected cells in the $CADM^+$ subpopulations (D and N in the CADM1 vs. CD7 plot), based on the results of real-time PCR (PVL analysis), semiquantitative PCR analysis of the *HBZ* gene, and FISH analysis (Fig. 2 and Supplementary Fig. S2). Furthermore, the CADM1 versus CD7 plot was shown to discriminate the three subpopulations more clearly than the CD3 versus CD7 plot (Fig. 1). Clonality analysis of ATLs and asymptomatic carriers (Fig. 4A and B) revealed that $CADM1^+$ subpopulations (D and N) contained

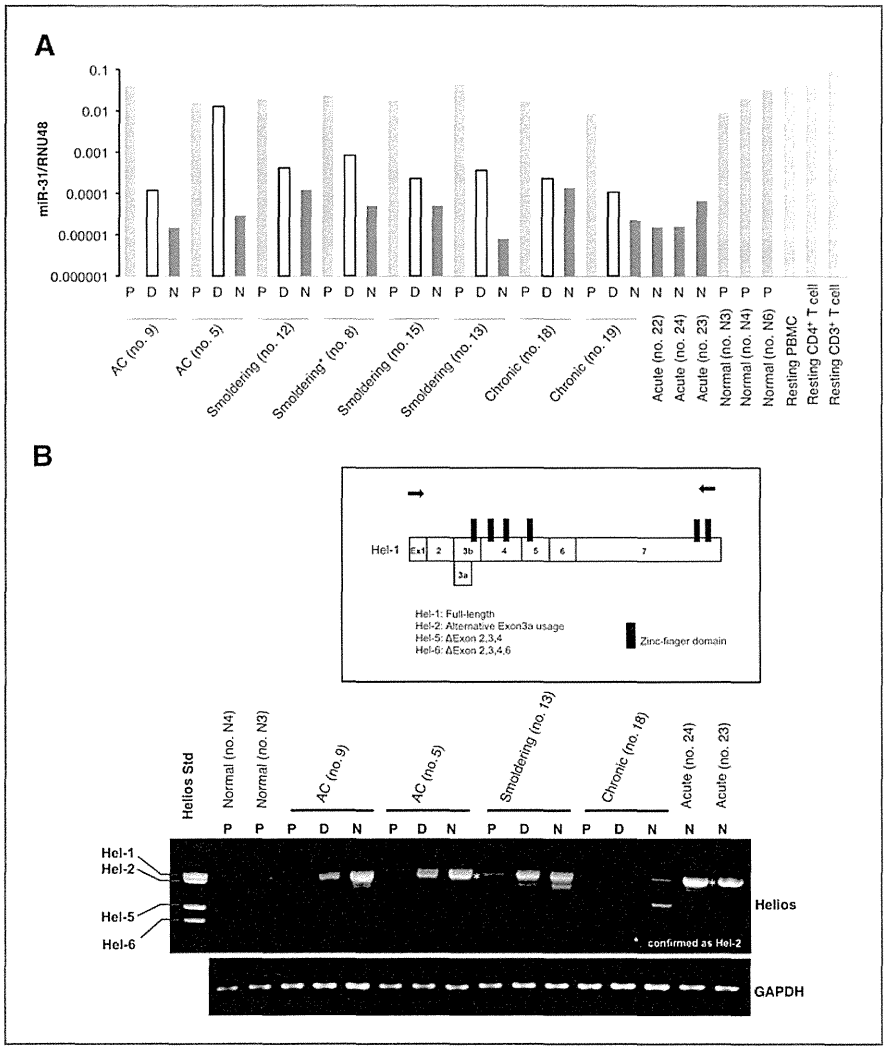

Figure 6. Gene expression pattern in the CADM1/CD7 subpopulation. A, miR-31 expression levels quantified by TaqMan-based real-time PCR. Total RNAs derived from each subpopulation were isolated and analyzed by RT-real-time PCR. RNU48 levels were also measured as an internal normalizer. *Smoldering (no. 8), this patient was considered to be at the asymptomatic carrier/smoldering borderline, because the proportion of abnormal lymphocytes fluctuated around 5%. On the day of sampling, the patient's hemogram showed 6.5% abnormal lymphocytes. B, expression analysis of *Helios* transcript variants in the subpopulations of normal controls ($n = 2$), asymptomatic carriers ($n = 2$), and ATLs (smoldering-type ATL, $n = 1$; chronic-type ATL, $n = 1$; acute-type ATL, $n = 2$). Comparisons of transcript variants among the P, D, and N subpopulations were performed by RT-PCR using primer sets specific for full-length *Helios* cDNA (top). The primer locations for *Helios* PCR are indicated by arrows in the schematic representation of *Hel-1*. The amplified cDNA (asterisk) was confirmed to be the *Hel-2* variant. The *Helios* standard (left lane), a mixture of cDNA fragments of *Hel-1*, *Hel-2*, *Hel-5*, and *Hel-6*, was used as a size indicator for each transcript variant. The glyceraldehyde-3-phosphate dehydrogenase (*gapdh*) mRNA was analyzed as an internal control (bottom).

clonally expanded HTLV-I–infected cells, whereas cells in the P subpopulation ($CADM1^-$) did not show clonal expansion in this analysis. Current molecular analyses of ATL cells have been limited to HTLV-I–infected cell lines and primary cells from acute/lymphoma type ATL, because in these cases, the predominant expanding clones are readily available with relatively high purity. However, the separation of clonally expanding ATL cells from indolent ATLs and asymptomatic carriers has not yet been achieved. The CADM1 versus CD7 plot from FACS allows efficient purification of such clones *in vitro*.

In an unsupervised clustering analysis of the gene expression data, the D and N subpopulations of asymptomatic carriers/indolent ATLs were grouped together, suggesting that the biologic characteristics of these subpopulations are similar (Fig. 5A and B) but distinct from the N subpopulation of acute-type ATLs (Fig. 5D). These results support the notion that in indolent ATLs and even in asymptomatic carriers, the D and N subpopulations are clonally expanding cells representing the intermediate oncogenic stage. Although the D and N subpopulations have similar gene expression profiles (Fig. 5C), there are potentially important differences distinguishing these subpopulations, according to the apparent decrease in the D subpopulation and increase in the N subpopulation that were observed as the disease progressed from indolent to acute-type ATL (Fig. 3). Detailed analysis of the genomic and epigenomic differences between these two subpopulations will provide us with information about the genomic and epigenomic lesions that are involved in disease progression. Another important finding is that the expression profiles of cells in the N subpopulation of indolent and acute-type ATLs showed significant differences, even though the majority of the genes were common to both groups (Fig. 5D). Characterization of the genes that show distinct expression patterns will reveal the molecular events that contribute to the progression from indolent to aggressive ATLs.

To address whether the emerging molecular hallmark of ATL was conserved in the novel subpopulations identified, we examined the miR-31 level and *Helios* mRNA pattern in sorted subpopulations (Fig. 6). Through integrative analyses of ATL cells, we recently showed that the expression of miR-31, which negatively regulates noncanonical NF-κB signaling by targeting NIK, is genetically and epigenetically suppressed in ATL cells, leading to persistent NF-κB activation, and is thus inversely correlated with the malignancy of the cells (31). The miR-31 levels in the P subpopulations in asymptomatic carriers and indolent ATLs were as high as those in normal P subpopulations, PBMCs, and resting T cells, whereas those in the D subpopulations decreased significantly and those in the N subpopulations were as low as in acute-type N subpopulations (Fig. 6A). Previously, we also identified ATL-specific aberrant splicing of *Helios* mRNA and demonstrated its functional involvement in ATL (32). As shown in Fig. 6B, the *Hel-2* type variant, which lacks part of exon 3 and thus lacks one of the four DNA-binding zinc-finger domains, accumulated in the D and N subpopulations of asymptomatic carriers and indolent ATLs, and was dominantly expressed in the N subpopulation of acute-type ATLs. Collectively, the molecular abnormality of ATL cells became evident in the gradual progression from P to D to N, even in asymptomatic carriers, strongly supporting the notion that the CADM1/CD7 expression pattern correlates with the multistep oncogenesis of ATL.

One of the more remarkable findings in the expression profile analysis was that the D and N subpopulations of asymptomatic carriers clustered within the same group as those of the indolent ATL cases (Fig. 5A and B). The asymptomatic carriers used in this analysis had high PVLs and relatively high proportions of the D and N subpopulations (Supplementary Table S1). In addition, mono- or oligoclonal expansion of the HTLV-I–infected cells was demonstrated in these cases. HTLV-I–infected cells in the D and N subpopulations of these asymptomatic carriers comprise clonally expanding cells that are potentially at the premalignant and intermediate stages according to their clonality, comprehensive gene expression profile, miR31 expression, and aberrant RNA splicing, all indicating that they can be categorized as asymptomatic carriers with high risk of developing into ATL, requiring careful follow-up (15, 30, 33, 34). Our flow-cytometric analysis of PBMCs from asymptomatic carriers using the CADM1 versus CD7 plot may provide a powerful tool for identifying high-risk asymptomatic carriers. Certain indolent ATL cases are difficult to distinguish from asymptomatic carriers, according to Shimoyama's criteria based on the morphologic characteristics determined by microscopic examination. Characterization of peripheral blood T cells by the CADM1 versus CD7 plot may provide useful information for clinical diagnosis.

According to Masuda and colleagues, manipulation of *CADM1* gene expression in leukemic cell lines suggested that CADM1 expression confers upon ATL cells tissue invasiveness and a growth advantage (35). The mechanism by which HTLV-I infection regulates CADM1 expression and the significance of CADM1 expression in ATL oncogenesis will require clarification by future studies.

Finally, as summarized in Supplementary Fig. S5, we demonstrated that (1) HTLV-I–infected and clonally expanded cells are efficiently enriched in $CADM1^+$ subpopulations; (2) the proportions of the three subpopulations in the CADM1 versus CD7 plot, discriminated by CADM1 expression and stepwise downregulation of CD7, accurately reflect the disease stage in HTLV-I infection; and (3) the $CADM1^+CD7^{dim/neg}$ subpopulations are at the intermediate stage of ATL progression and can be identified even in asymptomatic carriers. These findings will help to elucidate the molecular events involved in multistep oncogenesis of ATL.
